The number of trap captures was few at the inception of the survey in comparison to the number of captures resulting from the rolling of natural cover. However, the number of trap captures increased as the project continued until they accounted for most daily captures (Fig. 2). The initial decrease in the numbers of salamanders in traps and under natural cover may have resulted from their refugia being disturbed on a constant basis for the first eleven survey dates. On the last three survey dates, which were each a month apart, the number of salamanders under each type of refugia increased and the number of salamanders under natural cover approached pre-survey levels. This positive trend is probably due to the decrease in disturbance to refugia as well as a possible increase in activity. The PC traps were more effective than all other traps in terms of total captures and became the most overall productive method as the study continued. This trend may be the result of salamanders having more time to find the traps and use them as refugia. Forty-six (63%) of the 73 salamanders found in the PC traps were either in or under the PVC, which may indicate a microhabitat preference.

A potential bias of the PC trap is that it depends on animals to select it as refugia and may not be equally effective for species with differing microhabitat preferences. This bias is evident in the number of the total larval *P. ruber* that were found in PC traps (N = 59) as compared to the combined total of coverboards and PVC traps (N = 22). Another possible bias was exhibited by *D. conanti*, which were present only under coverboards.

One major advantage of the PC trap was that it could be left unattended for an indefinite amount of time without any mortality because the animals were able to escape. This allows much more flexibility in trapping schedule and much less constant upkeep when compared to techniques such as drift fences that must be checked daily (Gibbons and Semlitsch 1981). Although drift fences are an effective way of collecting species moving from one finite area to another such as a seasonal wetland, they may not be practical to use in long and thin habitats such as springs and streams that cannot be surrounded easily. Drift fences may also fail to capture salamanders that are able to climb out of pitfalls or over fences. Ryan et al. (2002) suggested that a combination of census techniques should be used when monitoring herpetofaunal communities to account for the maximum number of species. The PC trap, while efficient in sampling salamanders in its immediate area and habitat, is not designed to be an all-inclusive, mass sampling technique such as a drift fence. Instead, it is most useful when sampling fully or semi-aquatic salamanders in or in very close proximity to water on a sporadic sampling schedule.

Acknowledgments.—We thank J. R. and S. N. Luhring for their financial support and J. R. Luhring especially for many hours of manual labor. We thank the Georgia-Carolina Council of the Boy Scouts of America, P. Patton, and the Powell family for access to the study site. We thank J. W. Gibbons, J. D. Willson, C. T. Winne, A. E. Liner, and S. H. Schweitzer for their review of the manuscript and editing suggestions. We thank S. B. Castleberry, M. R. Boehm, and G. J. Graeter for their comments and insight. We thank J. R. Pittard and "the Samanthas" for assistance in the field. The procedures used in this study were approved by the University of Georgia animal care and use committee (A2003-10024, "Reptile and amphibian research—general field studies"). An Effective and Durable Funnel Trap for Sampling Terrestrial Herpetofauna

JEFFREY R. ROW
and
GABRIEL BLOUIN-DEMERS*

The global population decline of amphibians has attracted much international attention (Alford and Richards 1999). Although less attention has been paid to reptile populations, they appear to be declining at a faster rate than amphibian populations (Gibbons et al. 2000). Part of the discrepancy in attention between the two groups is due to the difficulty in estimating the population trends of reptiles. Reptiles tend to be secretive, solitary, and dispersed, making them difficult to sample, and these traits hinder long-term mark-recapture studies that are necessary to generate population trends.

To study the population ecology of terrestrial herpetofauna, researchers have employed various techniques such as timed searches, cover boards, and drift fences with pit fall traps or funnel traps (Renken et al. 2004; Ryan et al. 2002). Although all of these methods are effective, drift fences with funnel traps catch the largest species diversity and the most individuals (Ryan et al. 2002), especially for reptiles. Here we present our design for an effective, light, and durable funnel trap.

Species that aggregate for hibernation allow for a unique opportunity to acquire reliable population size estimates (Blouin-Demers et al. 2000; Prior et al. 2001). Each spring since 1996, we have sampled a population of Black Ratsnakes (*Elaphe alleghaniensis*) at the Queen's University Biological Station (150 km S of Ottawa, Ontario, Canada) by enclosing 12–18 hibernacula with perimeter fences fitted with funnel traps. We surround the hibernaculum with a wooden frame to which we staple heavy-gauge polyethylene plastic sheeting. We fold the plastic on itself twice before stapling and we staple through a piece of cardboard (3×10 cm) to prevent the plastic from ripping under wind force. We fold the plastic towards the inside of the fence at the bottom and pile rocks, sticks, and leaves on the fold until it is completely covered. We install one funnel trap along the fence when the enclosure has a diameter < 5 m and we install two traps diametrically opposed if the diameter of the enclosure is between 5 and 10 m. The enclosure and funnel traps allow a large proportion of the ratsnake population to be sampled: we capture ca. 200 individuals each spring (Blouin-Demers et al. 2000). We capture all size classes, from neonates (SVL = 250 mm, mass = 7 g) to adults (SVL = 1750 mm, mass = 1250 g). In addition, our funnel traps regularly capture (approximately 50 individuals per year) the other eight species of snakes encountered at our study site that use ratsnake hibernacula: *Nerodia sipedon, Thamnophis sirtalis, T. sauritus, Storeria dekayi, S. occipitomaculata, Diadophis punctuatus, Liochlorophis vernalis,* and *Lampropeltis triangulum*.

We construct the cylindrical frame of the trap and the funnel

with 1.27 cm (0.5 inch) hardware cloth (18–20 wire gauge) fastened with cage rings (these materials are commonly available at farm supply stores). We shape the funnel to be ca. 60 cm long, with a large opening of diameter > 30 cm and a small opening of diameter ca. 5 cm. We attach the funnel to a square piece (60 cm × 60 cm) of 1.91 cm (0.75 inch) plywood with a 30 cm circular hole cut 5 cm from the bottom (Fig. 1). The funnel is thus 5 cm above the ground after installation, but because we pile rocks, sticks, and leaves on top of the plastic sheeting we use as fencing, the opening of the funnel is actually level with the substrate (Fig. 2). We push the funnel from the outside through the opening in the plywood until it fits tightly and then cut, flatten, and secure (with 8 mm staples) the outer rim of the funnel to the plywood (Fig. 1). The diameter of the trap is also 30 cm, allowing us to use the plywood circle (cut out for the funnel) as the back of the trap.

To allow the capture of small snakes and to dissuade larger snakes from pushing their heads through the hardware cloth, we wrap the trap and funnel with aluminum window screening. We overlap the screening ca. 10 cm and sew it to the hardware cloth with aluminum wire (20–22 gauge), using 2-cm long stitches. The window screening and hardware cloth can both be purchased in 122 cm (4 feet) width, which is a convenient trap length.

After sewing the window screening to the trap, we install the

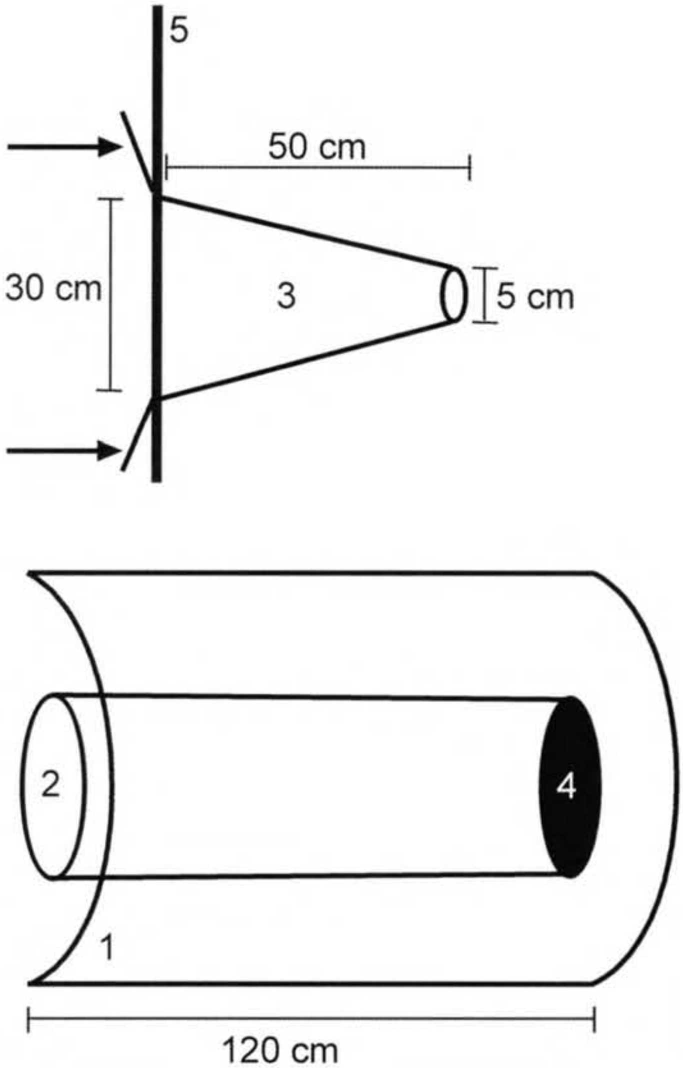

FIG. 1. Diagram of a simple and durable funnel trap. The trap (2) and the funnel (3) are made out of 1.27 cm (0.5 inch) hardware cloth and surrounded with aluminum window screening (1). The support for the funnel (5) and the back of the trap (4) are made with 1.91 cm (0.75 inch) plywood. The funnel is pushed through the hole in the support and then cut, flattened, and secured with staples around the edge of the funnel (arrows).

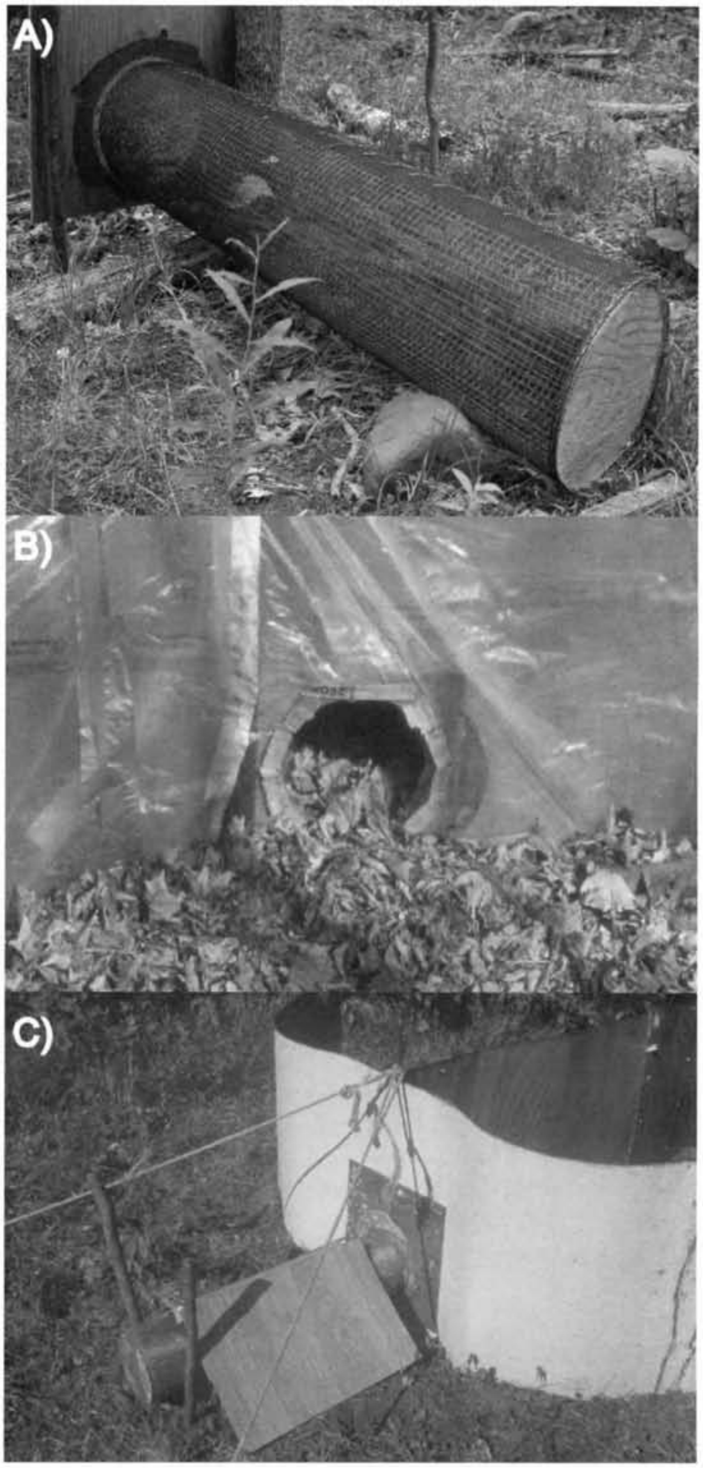

FIG. 2. Photographs of the simple and durable funnel trap (A), of the accumulation of debris on the plastic fencing that allows the funnel to be level with the substrate along a perimeter fence (B), and of the trap in use at the end of a metal drift fence with leads (C).

plywood circle at the back of the trap and secure it with 8 mm staples. It is important to attach the back of the trap last because it facilitates sewing the screening and the staples can secure both the hardware cloth and the mesh to the back of the trap.

Finally, we coat the small opening of the funnel with two-part epoxy (we found Plasti-Dip to be much less durable than epoxy). We dip the end of the funnel multiple times to build a thick coat. This serves two purposes: it makes the funnel more durable by hardening and securing the window screening and it covers sharp ends from the cut window screening which could injure snakes or deter them from entering the trap.

The trap is pushed tight against the funnel and secured by attaching a rope to the plywood on each side of the funnel (through two drilled holes) and passing that rope around the back of the trap. Because the trap is made of screening and hardware cloth, a visual inspection of the trap is sufficient to detect the presence of animals. When animals are captured, we detach the retaining rope, pull the trap back and quickly surround the opening of the trap with a snake bag (we use a pillow case). We gently raise the back of the trap until the animals slide in the bag. To prevent bites when dealing with venomous snakes, one could empty the trap in a hard plastic bucket or a garbage can instead of a bag.

To prevent overheating, we ensure that animals have shade by covering one end of the trap with a tarp or plywood scraps. Only one end is covered, as covering the whole trap could impede airflow and also lead to overheating.

Our funnel trap was inspired by earlier versions that were made solely of window screening held with office staples (e.g., Enge 1997), but we found those too flimsy for our purpose. The addition of hardware cloth, epoxy, and plywood does not add much weight and retains the effectiveness of earlier designs, but renders the traps more durable (some of our traps have been in service for 10 years) and better able to handle numerous large snakes (Fig. 2). Although we designed those traps to be placed on perimeter fences, they are versatile and can be placed at the end of a drift fence with leads (Fig. 2) or can be modified easily into a two-ended funnel trap (by the addition of a second funnel) to be placed at the center of a fence. Compared to box designs, we believe our mesh design is advantageous because it is light and see-through, but we think it is also more effective because it allows airflow. Airflow is likely a cue animals use to find an escape hole along a fence. If one makes many traps, the cost will be < US $20 per trap because the materials can be purchased in large quantities (e.g., full plywood sheets, 30.5 m (100 feet) rolls of hardware cloth and window screening). In conclusion, the traps can be used to catch a variety of terrestrial herpetofauna in numerous environments.

Acknowledgments.—Funding was provided by the Natural Sciences and Engineering Research Council of Canada, the Ontario Ministry of Natural Resources, and Parks Canada. We are grateful to R. Reed for his comments on our manuscript.

Using Deep-Water Crawfish Nets to Capture Aquatic Turtles

BRAD M. GLORIOSO

The most primitive method used to capture turtles is by hand, and a variety of hand capture methods appear in the literature (Cagle 1950; Carpenter 1955; Marchand 1945). Non-baited traps, particularly basking traps of various forms, have also been used in many turtle studies (Cagle 1950; Lagler 1943; Petokas and Alexander 1979; Robinson and Murphy 1975). The most popular baited-trap method is the hoop net, originally described by Legler (1960), and later refined by others to suit their specific needs. Since Plummer (1979) reviewed collection methods for turtles, many individuals have improved earlier trap designs and developed innovative capture techniques (e.g. Kuchling 2003; Sharath and Hegde 2003). Here we describe a novel technique that uses baited deep-water crawfish nets to capture carnivorous or omnivorous turtles. We include some preliminary data using this technique and discuss the potential advantages and disadvantages of these nets over traditional hoop nets.

Two dozen custom-made deep-water crawfish nets were purchased for US $75/dozen from a private dealer in Chalmette, Louisiana. Deep-water crawfish nets were constructed from a 50.8 cm diameter stainless steel ring (4.8 mm diameter) to which 16 mm black-dipped mesh was attached loosely to form a pocket (Fig. 1). Three 30.5 cm ropes were attached to the steel ring at equal distances from each other and were tied together at the other end to form a knot. A 5.1 cm diameter, 1.9 cm thick cork was attached above the knot followed by another knot to keep this cork in place. When placed in water, the cork suspended the three ropes above the mesh and minimized interference caused by turtles attempting to feed. A larger, second cork (5.7 cm in diameter and 3.8 cm

FIG. 1. Illustration of deep-water crawfish net.

thick) was positioned 91.4 cm above the smaller, first cork. The larger cork floated on the water surface and was used as a "catch" to extract the net from the water with a hollow aluminum pole (3.8 cm diameter, 195.6 cm long). Two stainless steel rods (6.4 mm in diameter) were attached on opposite sides of the same end of the aluminum pole (Fig. 2). The rods were 30.5 cm long, but extended only 15.2 cm beyond the pole. For added strength the remaining length of the rods was placed inside the aluminum pole and secured tightly by hammering flat the end of the pole. Both rods were slightly curved to prevent the large cork from falling off as the net is pulled from the water. The distance between the rods was 2.5 cm at the point they contacted the pole, but increased to 3.5 cm toward their end. The greater distance at the end of the rods facilitated grabbing the large cork, and as the net was pulled from the water, the cork slid down to the base of the rods where they contacted the pole. The point where the rods contacted the pole was the strongest part of the pole, and the strain of picking up nets rested on this position, not on the end or middle of the rods.

Each net was baited with chicken backs or leg quarter portions purchased from a local grocery. Each net was equipped with a center string for bait attachment, but to achieve longer bait life, a standard shower curtain clip was attached to the center of each net. The thickest part of the chicken back was pushed through the open clip, snaking the clip through the thin bone as many times as possible for a firm attachment, and then the clip was snapped close. Large turtles can remove poorly secured bait, and straighten clips while feeding; therefore, extra clips and replacement bait were required for an entire day of trapping.

Deep-water crawfish nets were set in waters ranging in depth from 15.2 cm to 121.9 cm. Spacing between nets was variable and depended primarily on depth and clarity of the water body. In murky, lentic waters (e.g., canals, ponds, sloughs, etc.) nets were positioned close together. In clear, lotic waters (e.g., rivers, streams, etc.) the distance between nets was increased. The nets rested flush with the substrate to reduce the chance of turtles, especially mud and musk turtles, from feeding beneath the net. To accomplish this, the aluminum pole was used to clear vegetation or debris from the water. After positioning the net, the larger cork was placed to one side of the net in a position to be easily grabbed with the rods of the aluminum pole. If the habitat allowed, the larger cork was placed out of the water on the bank or vegetation. Only in deep water was the larger cork ever directly above the net.

When using the pole to check nets, care was taken to minimize disturbance to the water surface, as this alarmed feeding turtles. To check nets, the larger cork was grasped between the rods, and then the cork was pulled straight up, and over to shore with one quick, fluid motion. Some turtles attempted to crawl or swim out of the net as it was picked up. Thus, checking nets was most efficiently accomplished with two individuals: one individual picked up the net and the second individual used a dipnet to catch any turtles that fell out of the net as it was being moved to land. Larger turtles (e.g., *Chelydra serpentina*) did not always completely enter the net while feeding. However, as the net was being lifted from the water, larger turtles often had their jaws firmly attached to the bait and could be lifted, albeit temporarily, from the water. If a second person was present with the dipnet ready, the turtle could be netted.

The frequency of checking nets depended on a variety of environmental variables, including habitat type, weather, water depth, water clarity and turtle behavior. Initially, nets should be set for at least fifteen minutes before checking to allow the scent of the bait to spread and attract turtles. However, because the scent was generally detected quickly in smaller lentic waters, nets needed to be checked every ten minutes. If feeding activity was low, more time between checking nets was required. In clear, lotic waters turtles could be observed feeding. Thus, to avoid disturbing feeding turtles, stealth was required in approaching and picking up the net. As turtles fed on the bait, oils and lipids rose and the presence of oil or small pieces of chicken fat at the water surface usually indicated feeding. Typically, the more oils at the surface, the larger the turtle (or more than one turtle) that was feeding. Also, larger turtles sometimes caused the larger cork at the surface to move while feeding in the net.

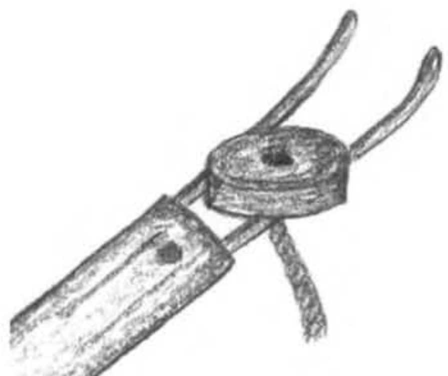

FIG. 2. Illustration of terminal end of aluminum pole showing position of steel rods used to extract deep-water crawfish nets from water via the large cork.

This technique has captured seven turtle species in several different aquatic habitats, including drainage canals in St. Bernard Parish, Louisiana (*Kinosternon subrubrum*, *Sternotherus odoratus* and *Trachemys scripta*), floodplain ponds and the main channel of the Stones River in Rutherford County, Tennessee (*S. odoratus*, *T. scripta*, *Apalone spinifera*, *C. serpentina*, and *Graptemys geographica*), and a roadside slough adjacent to Reelfoot Lake in Lake County, Tennessee (*K. subrubrum*, *S. odoratus*, *T. scripta*, *C. serpentina*, and *Chrysemys picta*). At the roadside slough (36°21.150'N, 89°24.920'W), 16 deep-water crawfish nets were used on 25 September 2004 for eight hours (0900–1700 h). All 16 nets were set from the shore in a straight (ca. 190 m) stretch of the slough. The total catch was 125 turtles with the following counts: 111 *S. odoratus*, 8 *C. picta*, 5 *T. scripta*, and 1 *C. serpentina*.

The largest turtle captured using this technique was a *C. serpentina* with a plastron length of 234 mm and a mass of 10.25 kg. This large turtle was captured with the aid of a dipnet, as it was not entirely within the net when it was pulled from the water. *Chelydra serpentina* exceeding 10 kg fed in the nets, but managed to escape during net retrieval. If the diameter of the ring for the nets were increased, this might increase chances of capturing these larger snapping turtles. *Trachemys scripta* ranging in size from 42 to 235 mm plastron length and 19.5 to 2575 g have been captured using deep-water crawfish nets. The smallest turtle captured was a hatchling *S. odoratus* with a plastron length of 16.6 mm having a mass of 3.2 g. Therefore, these nets are suitable for capturing nearly all size classes of carnivorous/omnivorous aquatic and semi-aquatic turtles. They are especially adept at capturing *S. odoratus*.

These nets have a number of advantages over traditional hoop nets: 1) With this active method of catching turtles exact times of feeding can be ascertained, which could not be done with any precision with hoop nets. 2) They are less expensive and less bulky than hoop nets. In general, two dozen deep-water crawfish nets takes up less space than a traditional hoop net. 3) Turtles can be captured in extremely shallow waters with these nets. 4) With hoop nets, there have been reports of turtle injury or mortality resulting from prolonged periods within the net (e.g., Barko et al. 2004; Dodd 1989). The likelihood of injury using deep-water crawfish nets is significantly reduced because turtles are not 'trapped', and nets are checked frequently. 5) Lastly, unlike hoop nets, there is little chance of theft or sabotage to deep-water crawfish nets that you are actively checking from the shore.

Hoop nets do have some advantages over deep-water crawfish nets. Because hoop nets only have to be baited, set and checked every so often, the time required to sample in this manner is significantly less than sampling using deep-water crawfish nets. The actual trapping of hoop nets is done passively as opposed to the active method of using deep-water crawfish nets where the investigator must be present. Hoop nets are advantageous in situations where trapping must be done from a boat. We suggest that deep-water crawfish nets will not work well in these situations because the surface disturbance created by a moving boat would scare feeding turtles out of the net before it could be checked. Also, hoop nets are useful in trapping turtles that feed at night. By comparison, deep-water crawfish nets are more difficult to use at night. However, we increased our trapping success at night by wearing headlamps and affixing reflective tape to the large cork and rods of the aluminum pole.

Fluorescent Powder Pigments as a Harmless Tracking Method for Ambystomatids and Ranids

TRACY A. G. RITTENHOUSE*

Many amphibian species require both aquatic and terrestrial habitats to fulfill their biphasic life cycle. Research often focuses on processes and life stages occurring in aquatic habitats because the high concentration of animals facilitates the logistics of research and strong density dependence in larvae suggests that populations may be regulated by this life stage (Wilbur 1980). However, adult amphibians use extensive amounts of terrestrial habitat (Semlitsch and Bodie 2003), populations worldwide are declining due to habitat loss (Stuart et al. 2004), and new evidence suggests that the juvenile or adult life stages may be important in regulating populations (Biek et al. 2002). Efforts to study amphibians in terrestrial habitats have increased greatly in the last decade, but limitations in finding, capturing or tracking animals away from breeding sites still restrict our ability to answer basic ecological questions in terrestrial habitats.

Fluorescent powdered pigments (hereafter referred to as powder) have been used to track a variety of organisms including small mammals, reptiles and larval amphibians (Blankenship and Bryan 1990; Fellers and Drost 1989; Ireland 1973; Lemen and Freeman 1985). More recently, powder has been used to track amphibians in terrestrial habitats (Birchfield and Deters 2005). The primary assumption of all tracking studies is that the tracking method does not affect the animal (White and Garrott 1990; Millspaugh and Marzluff 2001). Experimentally testing this assumption is an important step to validate this technique. While reports of negative effects of powder tracking are rare, the inhalation of powder was reported to cause moderate levels of histiocytic pneumonia in deer mice, *Peromyscus maniculatus* (Stapp et al. 1994), and powder can persist in the environment for long periods of time (Halfpenny 1992). Studies examining the effects of powder on amphibians are limited (but see Berger 2000; Eggert 2002).

We experimentally tested both short-term (i.e., powder present on the skin) and long-term effects of powder on both recently metamorphosed Wood Frogs, *Rana sylvatica*, and Spotted Salamanders, *Ambystoma maculatum*. We chose the rate of water loss as the short-term response because water regulation is a critical process for amphibians in terrestrial habitats and because amphibian skin affords virtually no protection from desiccation (Ray 1958; Thorson 1955). The large surface area to volume ratio in recently metamorphosed juveniles causes water loss to be a greater threat to juveniles than adults (Thorson 1955). In addition, the small particle size of the powder coating the skin may alter the flow of water across the skin and thus presents a possible mechanism for how the powder could affect an amphibian. We chose survival and growth as our long-term responses because these variables provide an indication of the general health of an amphibian and relate to demographic processes.

Materials and Methods.—Wood Frog egg masses were collected from the Daniel Boone Conservation Area in Warren County, Missouri, USA, on 6 March 2004. After hatching, tadpoles were reared until metamorphosis in outdoor 1000-liter cattle tank mesocosms stocked with 1 kg leaf litter and zooplankton inoculum. Larval Spotted Salamanders were collected (using dip nets) from the Baskett Wildlife Research Area in Boone County, Missouri, USA, on 25 August 2004 and maintained in aquaria with aerated pond water until metamorphosis. Newly metamorphosed frogs and salamanders were housed in aquaria with moist sphagnum moss at the University of Missouri and fed crickets *ad libitum*.

Two long-term experiments tested for differences in growth and survival of Wood Frogs and Spotted Salamanders covered and not covered with powder. For the experiment on frogs, 70 individuals were randomly assigned to six treatment groups based on powder color on 6 June 2004: blue (N = 10), green (N = 10), orange (N = 10), yellow (N = 10), red (N = 10), and a no powder control (N = 20). For the experiment on salamanders, 20 individuals were randomly assigned to two treatment groups on 20 September 2004: red (N = 10) and a no powder control (N = 10). Treatment consisted of dipping each individual in fluorescent powder pigments (Radiant Color, Richmond, California, USA) until completely covered. Control animals were handled in a similar manner, except they were not dipped in powder. Animals were randomly assigned to an individual $17 \times 12 \times 9$ cm plastic container that contained moist sphagnum moss with a fiberglass window screen lid. All animals were fed approximately 18% of their body weight in small crickets each week, split between two feedings. Every two weeks for a six-week period all animals were weighed and the powder treatment was re-applied.

Two short-term experiments tested for differences in the rate of water loss between animals covered and not covered with powder. Similar procedures were followed for both the wood frog experiment on 12 August 2004 and the spotted salamander experiment on 9 November 2004. Animals were placed in a plastic container containing 0.5 cm of carbon-filtered water for approximately 12 hrs prior to the beginning of the experiment to ensure all animals were fully hydrated. The dehydration chamber consisted of a square chamber ($5 \times 5 \times 5$ cm) constructed of metal window screen (similar to Pough et al. 1983) that was suspended, exposing all sides to air and did not prevent animals from using water conserving postures. Animals were assigned to a powder treatment or control group according to the treatment that individual received during the long-term experiments, thus 20 frogs (i.e., $N_{control} = 10$ and $N_{red} = 10$) and 18 salamanders (i.e. $N_{control} = 10$ and $N_{red} = 8$) were tested. Using the same animals in both the short-term and long-term experiments did not bias our results because the data from the experiments were analyzed separately and because any potential carryover effects from the long-term experiments should increase the likelihood of detecting an effect in the short-term experiments. Each chamber was weighed, an animal was randomly assigned to the chamber, and the combination of the animal and chamber was weighed every 30 minutes for 120 minutes until animals lost approximately 15% of their body mass. Thus animals were not exposed to lethal dehydration levels: 30–35% for ranids

(Thorson and Svihla 1943); and 36–40% for ambystomatids (Pough and Wilson 1970; Ray 1958).

Changes in mass over six weeks for the long-term experiments and over 120 minutes for the short-term experiments were analyzed using repeated measures analysis of variance. Only animals without missing observations (i.e., individuals that survived the entire experiment) were included in the analysis of mass. Analysis of variance was used to test for the effects of the powder treatment on survival, with number of days alive as the response variable. All weights were obtained using a Mettler AT261 Delta Range electronic balance with readability of 0.01mg.

Results.—Growth between animals covered and not covered with powder did not differ for either Wood Frogs ($F = 0.19$, d.f. = 5,57, $P = 0.97$; Fig. 1a) or Spotted Salamanders ($F = 0.24$, d.f. = 1,17, $P = 0.63$; Figure 1b). A significant increase in mass occurred throughout the six weeks for both Wood Frogs ($F = 354.77$, d.f. = 3,55, $P < 0.0001$) and Spotted Salamanders ($F = 213.00$, d.f. = 3,15, $P < 0.0001$). No interactions between the powder treatments and time occurred (all $P \geq 0.40$). The number of days alive did not differ between frogs covered and not covered with powder ($F = 0.58$, d.f. = 5,64, $P = 0.71$), but seven frogs died throughout the course of the long-term experiment. Survival was 100% in the long-term salamander experiment, but one escaped and one from the red treatment died after the completion of the long-term experiment but prior to the short-term experiment. We believe the mortality occurred when animals were not feeding readily, because these individuals were the smallest at the initiation of the experiments.

Water loss between the control and powder treatments did not differ for either Wood Frogs ($F = 0.34$, d.f. = 1,18, $P = 0.57$; Fig. 2a) or Spotted Salamanders ($F = 0.49$, d.f. = 1,16, $P = 0.49$; Fig. 2b). Continuing the experiment until all animals had lost approximately 15% of their body mass produced a significant decrease in mass for both the frogs ($F = 590.04$, d.f. = 4,15, $P < 0.0001$) and the salamanders ($F = 442.29$, d.f. = 4,13, $P < 0.0001$). No interactions between powder treatments and time occurred (all $P \geq 0.34$). Survival was 100% in both short-term experiments.

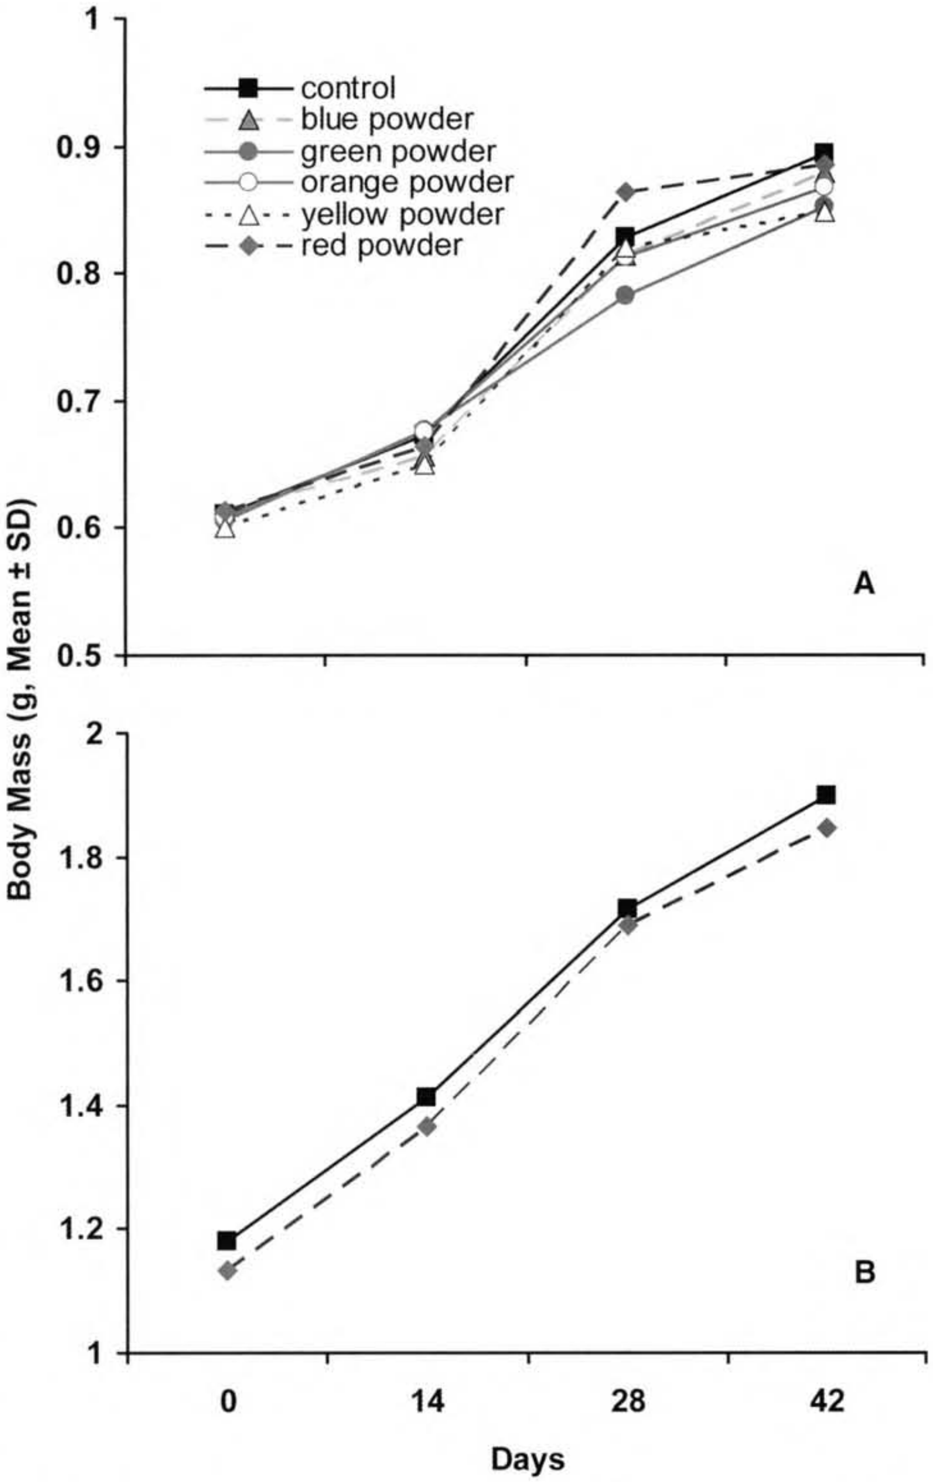

FIG. 1. Mean growth for each powder treatment during the long-term experiments for Wood Frogs (A) and Spotted Salamanders (B) at two week time intervals.

Discussion.—We did not detect any short-term or long-term effects of powder on either Wood Frogs or Spotted Salamanders. Growth and survival over a six-week period, as well as rates of water loss, were unaffected by being covered with powder. We suggest that being covered with powder is similar to being covered with other natural items, such as soil or organic debris, and conclude that powder is a harmless method for tracking ambystomatids and ranids in terrestrial habitats.

All experiments provided conditions that may cause the powder to be more stressful than animals would experience when powder is used to track amphibians in the field. First, animals in the laboratory had limited opportunity to remove the powder by rub-

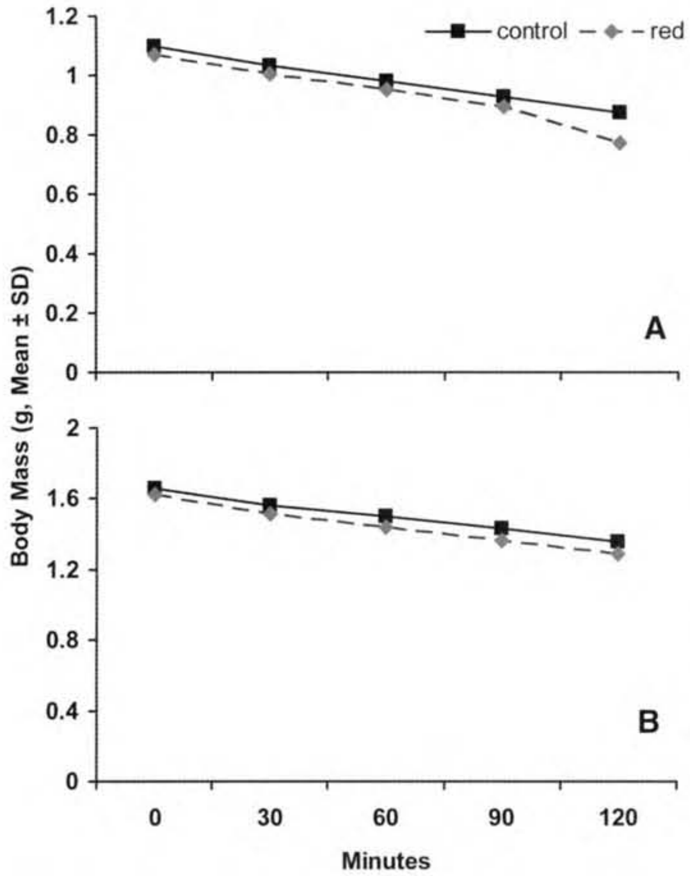

FIG. 2. Mean water loss for each powder treatment during the short-term experiments for wood frogs (A) and spotted salamanders (B) at 30 min time intervals.

bing against vegetation or hopping around. This was especially true in the dehydration experiments where small enclosures restricted hopping movements and substrate was not provided. Animals in these experiments remained completely covered with powder for the entire 120 minutes. Although we did not observe any behavior that suggested animals were purposely attempting to remove the powder, animals in the long-term experiments lost the powder quickly, with powder visible on approximately 52% of the animals at 24 h after powder application and no powder visible on any of the animals at 3 days after powder application. Second, animals in the long-term experiments were exposed to the powder on three occasions. When powder is applied in the field, animals are often only covered with powder once, because the individual is not recovered after being released. We found no evidence that repeated exposure to the powder is harmful to amphibians.

Three tracking methods are primarily used for directly following amphibians in terrestrial habitats: radio-telemetry, thread-trailing, and fluorescent powder pigments. Each method has advantages and disadvantages. For example, although radio-telemetry allows a researcher to track an individual for the longest time period (e.g., 1–4 months depending on transmitter size) and longest distances (e.g., Bartelt et al. [2004] tracked *Bufo boreas* > 200 m), the cost of radio-telemetry is the greatest (US $150 per transmitter plus additional costs for receiving equipment) and risk to the animal can be the greatest (see Rittenhouse 2002 for mortality caused by transmitter implantation). Tracking amphibians with powder often provides the shortest movement paths of all the tracking methods; however, several benefits can make powder the preferred tracking method in many instances. Powder tracking results in a detailed description of the movement path (e.g., Birchfield 2002; Eggert 2002). Powder can be used on juveniles or species too small for other tracking devices and is relatively inexpensive (e.g., US $12 per one-pound can). However, a possible side effect to amphibians is the potential increase in visibility to predators that use color to locate prey. Although the optimum tracking method will vary based on the research objectives of a study, tracking amphibians with powder is an underutilized tracking technique that does not appear to detrimentally affect growth, water regulation or survival in the laboratory of ambystomatids or ranids. Therefore, this technique might be particularly useful when studying rare or endangered species.

Acknowledgments.—We thank E. Harper for raising the Wood Frogs to metamorphosis. J. Crawford provided thoughtful comments on the manuscript. Animals were captured under Missouri Department of Conservation Wildlife Collector's permits 12220 and 12227 and maintained under University of Missouri Animal Care and Use protocol 3368. Funding was provided by NSF grant DEB 0239943 to R. Semlitsch.

Measurement of color in reptiles can play a fundamental role in research areas as diverse as behavior, physiology, evolution, and ecology. For example, studies incorporating color have investigated the behavioral role of dewlap color in *Anolis* lizards (Macedonia et al. 2003; Thorpe and Stenson 2003), thermoregulation in desert reptiles (Norris 1967), sexual selection in chuckwallas (Kwiatkowski and Sullivan 2002), and predator evasion in agamid lizards (Stuart-Fox et al. 2004). These studies rely on the ability to accurately quantify body color.

There are a number of small portable spectrometers available that measure reflectance or radiance. Previous studies using spectrometers to measure the color of lizards and/or their backgrounds in the field typically used sunlight as the source of illumination (Macedonia et al. 2002, 2003). This approach can cause problems if the measurements are not taken under similar and constant conditions, as weather conditions, nearby vegetation, different microhabitats, seasons, and the time of day can result in drastically different radiance spectra of the animal or background being measured (Endler 1990, 1993). Consequently, moment-to-moment fluctuations in lighting conditions can cause errors and alter the radiance or reflectance output given by a spectrometer (Endler 1990, 1993). Thus, a method that eliminates or greatly reduces inconsistencies in lighting would provide far more consistent and repeatable measurement of reflectance or radiance. In particular, the exclusion of ambient light, which can change over short time periods because of movement of clouds or overhead vegetation (Endler 1993), would increase the constancy of reflectance spectra. Yet such a method has limitations when used in the field, because of the difficulty of removing all sources of ambient light. Until now these limitations have meant that study subjects have been returned to the laboratory to take controlled reflectance readings in a darkened room (Macedonia et al. 2002; Stuart-Fox et al. 2003, 2004). However, removing lizards from their natural habitat may result in stress responses, which could lead to skin-color changes, as reported in species that have the ability to rapidly lighten or darken their skin color, such as some agamids (Christian et al. 1996) and iguanians (e.g., Cooper and Greenberg 1992). When investigating background-color matching, such color changes may not be indicative of the lizard's typical body color.

We have designed and tested an opaque probe cover for use with a portable spectrometer that allows accurate and controlled measurement of reflectance in the field. We tested the reliability of this new method during a study of background-color matching in the painted dragon, *Ctenophorus pictus*. In this article we describe an effective method for measuring reflectance of virtually any species of lizard in the field with the aid of this probe cover. In fact, the methods described would have applicability across a wide range of animal taxa. Our methods are inexpensive, easily constructed, and portable.

Cover for Optical Fiber Probe.—Measures of reflectance were taken using an Ocean Optics USB2000 Miniature Fiber Optic Spectrometer® (Dunedin, Florida) and an illumination source was provided by a PX-2 Pulsed Xenon Lamp® (Dunedin, Florida), connected to the spectrometer by a standard reflection probe (200 µm diameter). The spectrometer and light source were then connected to a laptop computer via a USB cable for reflectance calculations using the Ocean Optics software package, OOIBase32.

We designed an opaque cover that attaches to the optical fiber probe, ensuring that only the light from the xenon lamp illuminates the target area. This cover was constructed from a large plastic drinking straw that fit snugly over the probe (Fig. 1). The straw was wrapped in layers of black duct tape to block out ambient light. One end of the straw was then cut to make a 45° angle at a distance of 1 cm from the end of the probe to the surface sampled (following Endler 1990). Once the probe was cut to size, several layers of duct tape were placed around the cut end of the probe to create a base (10 × 10 cm), which further reduced light from entering the receiving end of the probe. This base can be made to any size and/or shape to suit different-sized lizards. The resulting probe cover is flexible and after being placed on a lizard can be peeled backwards to ensure the probe is positioned in the desired location. The lizard is restrained by wrapping the base of the probe around the body until the measurement was made but we also recommend restraining the lizard while measurements are being taken (e.g., Rose et al. 2006). Additionally, a transparent probe cover was constructed to test the accuracy of the opaque-probe cover using the same methods described for the opaque cover, the only

difference being that clear tape was used instead of black duct tape to create a transparent rather than opaque cover.

All measurements were expressed relative to a white reflectance standard (> 95–98% reflectivity). Lizards were placed on a black backing during the readings to ensure that only the reflectance of the lizard was being measured. The probe cover, where it meets the surface being measured, has an area of 0.55 cm^2, meaning that the surface quantified would need to be at least this size to ensure all ambient light was eliminated. The area of color being measured with the opaque cover is equivalent to the diameter of the optical fiber aperture used (200 μm), with the area of light leaving the probe equal to 0.31 cm^2.

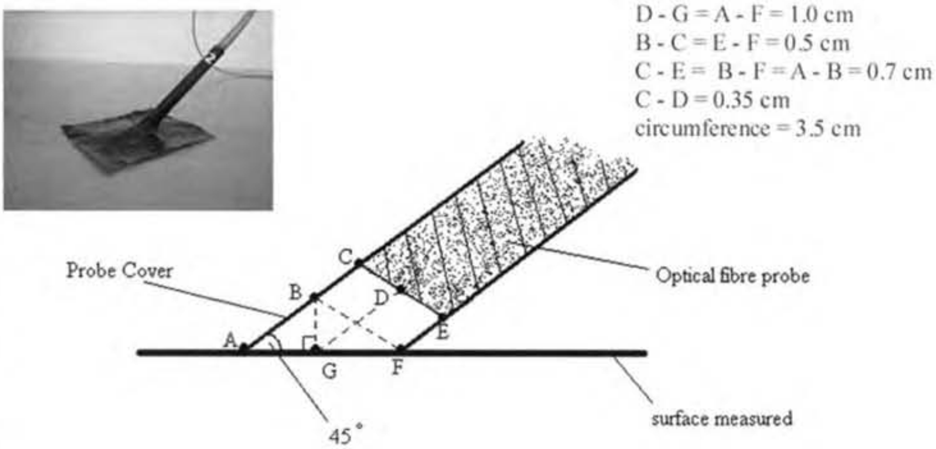

FIG. 1. Design of the cover for the optical fiber probe.

Testing the Efficiency of the Opaque Probe Cover.—To determine whether our opaque probe cover provided an improvement over measuring radiance in ambient light, we conducted an experiment using color standards. We tested the opaque cover by measuring color standards (blue, green, red, and yellow) in a darkened room, outdoors in full light, and outdoors under the shade of a tree. Three methods (no probe cover, transparent probe cover, and opaque probe cover) were tested in each light environment to determine if there were significant differences between spectral readings among the three methods.

In obtaining the spectral data, the parameters for each method could not be kept constant. The integration times for the spectral readings had to be adjusted (Table 1) to ensure that the reference calibration was not being saturated. As a result, we standardized the maximum height of the peak for the standard in scope mode to approximately 3500 counts and used the corresponding integration time.

The opaque probe cover was highly consistent across all three light environments (Table 1), as it did not require the integration time to be altered. The integration times for the opaque probe cover were also equivalent to the integration time needed without a probe cover in a darkened room. This suggests that the opaque cover can be used in a variety of light environments and still be equivalent to taking readings without a probe cover in a darkened room.

All spectral data presented throughout this study were analyzed from 320–720 nm. This range includes the spectrum visible to humans (400–700 nm) as well as some ultraviolet (UV) (below 400 nm) and infrared (above 700 nm) regions. This region was chosen for a study of the body color of *Ctenophorus pictus* because many animals see beyond the human spectrum, including birds (Bennett and Cuthill 1994; Hart et al. 2000) and some lizards (Fleishman et al. 1993).

The raw reflectance data were grouped into 10-nm bins for statistical analysis, which reduces the problem of non-independence of data points (Leal and Fleishman 2002; Macedonia et al. 2002; Thorpe and Stenson 2003). We analyzed the reflectance data by principal components analysis (PCA) to reduce the number of variables for analysis (Endler 1990; Macedonia et al. 2003). Three principal components (PCs) were extracted from the PCA combining the three methods of data acquisition (no probe cover, transparent probe cover, and opaque probe cover) for four color standards (blue, green, red, and yellow) across three lighting environments (darkened room, outdoors full-light, and outdoors shaded). The eigenvalues and percentage of explained variance were as follows: PC1 (17845.72, 69.43%); PC2 (5717.55, 22.24%); PC3 (1936.52, 7.53%). We compared the three measurement methods in each of the light conditions for each PC separately, using paired *t*-tests. In outdoor full light we found significant differences between using the opaque probe cover and no probe cover for PC2 (t_3 = -3.469, P = 0.040) and PC3 (t_3 = -7.950, P = 0.004), and between the opaque probe cover and the transparent probe cover for PC2 (t_3 = -3.856, P = 0.031) and PC3 (t_3 = -10.935, P = 0.002). In outdoor shaded light we found significant differences between using the opaque probe cover and no probe cover for PC2 (t_3 = -3.208, P = 0.049) and PC3 (t_3 = -7.027, P = 0.006) and between the opaque probe cover and the transparent probe cover for PC2 (t_3 = -4.711, P = 0.025) and PC3 (t_3 = -4.288, P = 0.023). In the shaded condition there was also a significant difference between using no probe cover and using the transparent probe cover in PC1 (t_3 = 3.350; P = 0.044). There were no significant differences among the three methods in a darkened room.

These results indicate that there are significant differences between using the opaque probe cover and using no probe cover or a clear probe cover across different lighting conditions, especially in terms of PC2 and PC3. These differences are most likely to be a result of changes in ambient light from the time when the white standard sample was recorded, and when the color standard was measured. This could be the result of changes in reflected radiation (e.g., cloud cover, vegetation), or experimental error such as subtle changes in the lizard's body position among readings. Nevertheless, the opaque probe cover performed most consistently across a range of lighting conditions, regardless of whether the ambient light conditions were varied.

Testing the Opaque Probe Cover on a Study Species.—We tested for dorsal background-color matching in two populations of *Ctenophorus pictus*. Five females were collected from the Little Desert National Park (36°34'02"S; 141°20'55"E; white sand population) and five were from the Murray Sunset National Park (36°34'46.5"S; 141°36'38"E; red sand population) in northwestern Victoria. Lizards were measured outdoors, under natural light

Table 1. Integration times (ms) needed in each light environment for each probe cover to obtain 3500 counts in scope mode.

	Integration Time (ms)		
Probe cover	Inside	Full light	Tree shade
No cover	110	30	70
Transparent cover	70	35	70
Opaque cover	110	110	110

conditions, using the opaque cover and then these measurements were repeated indoors in a darkened room without use of the probe cover, which is a more typical method of color measurement. To provide consistency in the tests, we used the same spectrometer settings across all measurements.

The lizards were warmed to 37.8°C immediately before reflectance was measured. This value was chosen as it lies within the two published mean active body temperatures of this species (34.4°C, Melville and Schulte 2001; 39.0°C, Mayhew 1963). Four reflectance readings were taken for each lizard on the dorsal surface of the body: head, between the shoulders, mid-back, and at the base of the tail. These locations encompass the range of dorsal color and pattern variance for this species. We measured the dorsal surface because we were interested in background-color matching. Readings on the mid-back of the lizard were taken slightly off center to avoid the black patterning along the middle of the back. This was achieved by folding back the flexible opaque cover as it was being placed on the back of the lizard to ensure the precise locality of reflectance readings.

A PCA reduced the data set to three axes, with eigenvalues and the percentage of explained variance as follows: PC1 (1658.77, 88.29%); PC2 (202.52, 10.78%); PC3 (10.52, 0.56%). To test for differences between using the probe cover outside and measuring reflectance inside, we used a one-way repeated measures ANOVA for each of PC1, PC2, and PC3. No significant difference was detected in using the probe cover outside in natural light, or taking reflectance measures in a darkened room without a probe cover for each PC score (PC1: $F_{1,9} = 0.380$; $P = 0.553$; PC2: $F_{1,9} = 0.006$; $P = 0.940$; PC3: $F_{1,9} = 2.766$; $P = 0.131$). A problem that we noted in taking the readings inside without the probe cover was the difficulty in estimating the constant 1-cm distance and 45° angle desired for taking readings.

Next, we measured the dorsal reflectance of 112 *Ctenophorus pictus* in the field using the opaque cover. Because *C. pictus* are easily caught in these sandy deserts, we could measure their reflectance immediately at the point of capture. We also measured the reflectance of the sand the lizard was on at the point of capture, thereby permitting estimates of background-color matching *in situ*.

Ctenophorus pictus is an ideal study species because they are easily caught within proximity of our field vehicle. Consequently, the light source could be powered by the vehicle's battery: a voltage transformer was plugged into the car's cigarette lighter, and a 25-m extension cord was attached to the transformer. This allowed us to measure the reflectance of lizards and their backgrounds up to 25-m away from the vehicle. Our method could be used in the field even without a support vehicle if researchers were willing to transport a spotlight or car battery into the field.

Our opaque probe cover provides an inexpensive easy to construct method to measure reflectance across that should prove suitable for a wide range of taxa. We have shown the advantages of measuring reflectance in the field. In addition, this method is applicable to measuring the reflectance of any surface > 0.55 cm^2. In the past, optical fiber probe covers have been used to hold the probe at a constant distance and 45° angle to the surface (Stuart-Fox et al. 2004; Thorpe 2002; Thorpe and Stenson 2003). However, these covers were not designed to block out ambient light from entering the surface being measured. Other studies have relied on attaching a ruler to the end of the probe to maintain a constant distance between the probe and the surface being measured (Macedonia et al. 2002, 2003). Our probe cover is an improvement on previous methods because, as well as providing constant distances between the probe and the surface of analysis, it also blocks out ambient light, making it suitable for repeatable measurements of reflectance in the field.

Acknowledgments.—We thank L. Revell for his assistance with the spectrometer and analysis. We are grateful to J. Van Buskirk and J. Ng for their advice and assistance. We are especially thankful for the valuable comments made by two anonymous reviewers. Permits for field work were provided by the Department of Sustainability and Environment Victoria (Permit No. 10002952), and the Department for Environment and Heritage South Australia (Permit No. E24870). Funding for this study was provided by ARC Discovery Grant (DP0452082) and Australian Society of Herpetologists Student Research Grant. This research was approved by The University of Melbourne Faculty of Science Animal Experimental Ethics Committee and The South Australian Wildlife Ethics Committee.

Numerous techniques have been used for restraining lizards including controlling by hand, anesthetizing (Nelson and Jayne 2001), and thermal cooling combined with the use of sticky tape (Hoefer et al. 2003). Restraining devices are often designed for use with members of specific genera (Poulin and Ivanyi 2003) or for lizards of a particular size (Hoefer et al. 2003). Such methods impose limitations on studies that seek to measure morphological characteristics of live lizards representing a broad range of body sizes.

Here we describe an effective technique for restraining various species of lizards that range in body size from 30–250 mm snout-vent length (SVL). Our technique reduces the time spent processing individual animals and may, therefore, minimize handling stress. Our method is easily constructed, inexpensive, and portable making it suitable for both laboratory and field studies. We used this restraining method successfully on three species of agamid lizards (Painted Dragon, *Ctenophorus pictus*; Mountain Dragon, *Rankinia diemensis*; and Bearded Dragon, *Pogona vitticeps*) and one species of gecko (Knob-tailed Gecko, *Nephrurus amyae*). Specifically, we provide detailed descriptions of the methods used to restrain *Ctenophorus pictus* in the field for morphometric analysis using digital photography.

Restraining Tray.—When using digital photography to conduct morphometric analyses it is critical to maintain all lizards in the same position for each image, and to provide an unobstructed view of the appendages. With this in mind, we designed a restraining tray using single-sided Velcro with an adhesive backing to hold the animal's body in place, and a plastic tray as the base. Strips of the hooked side of Velcro were stuck onto the tray, and thin strips of the looped Velcro were cut and the adhesive backing covered in flexible cotton material to avoid dirt and sand sticking to it. Lizards were placed onto the Velcro base of the tray and positioned as needed. We restrained lizards with one strip of Velcro placed firmly over the neck, plus a second strip just above the pelvic girdle (Fig. 1). In the case of juveniles or very small lizards, one strip of Velcro across the neck was adequate for restraint. We surrounded the base of hooked Velcro with strips of looped Velcro, which allowed the claws of the lizards to grip onto the base, ensuring that the limbs remained in the desired position.

Morphometric Analysis.—For the morphometric analysis of *Ctenophorus pictus*, we attached a clear plastic ruler to the restraining tray and a label was included in each image for identification purposes. We then took digital photographs of restrained individuals, ensuring that the ventral surface of the lizards was flat on the tray and that their body was straight (Fig. 1). At least one hind limb and one forelimb were physically extended on the restraining tray to ensure accurate measurement of limb proportions from the digital image. One advantage of digital images is that the photographs can be archived and accessed at any time for analysis.

Six measurements were taken for each lizard (N = 128): head length, SVL, axilla-groin distance, forelimb length, hind limb length, and tail length. Lizards measured included juveniles and adults of both sexes ranging from 31.2–77.9 mm SVL. All lizards measured were successfully restrained using our device, without a single lizard escaping or being injured.

Morphological analyses from the photographs were performed using ImageJ (v. 1.32j) digital image analysis software (Rasband 2004). We tested the accuracy of measuring a subset of the morphological characters by comparing the measurements made with the digital images and analysis software to those recorded with digital calipers. The measurements using ImageJ differed by 1.7% (N = 20) from caliper measurements, which would represent a 0.9 mm difference in the measurement of a 50 mm SVL lizard.

The restraining tray proved ideal for the wide range of sizes of agamid lizards in our study. Our success across these agamid species may be a result of the rough scales and well-defined neck in these lizards, which facilitated holding them in place with the Velcro strips. Hence, this method should be applicable to most

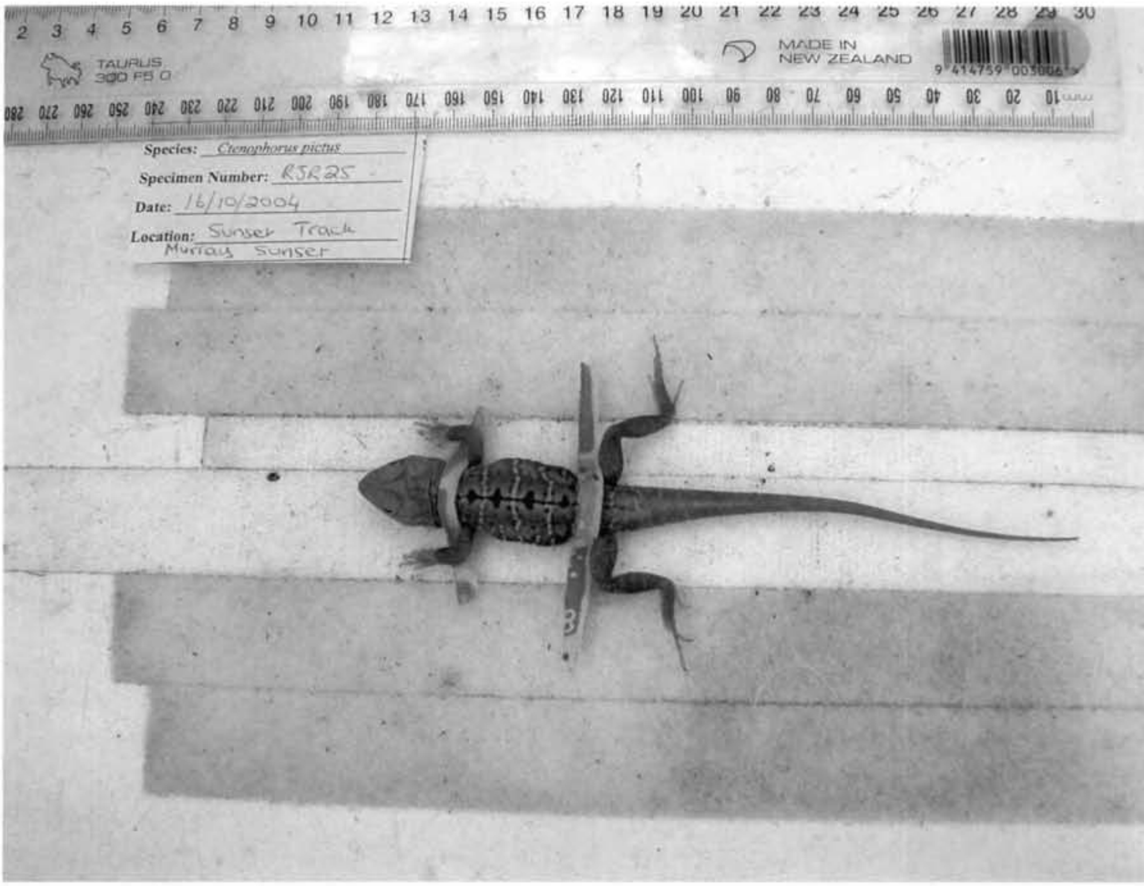

FIG. 1. Digital image of an adult male *Ctenophorus pictus* positioned on the restraining tray.

lizard taxa with rough scales and defined necks, such as agamids, iguanids, cordylids, some lacertids, and many geckos. In fact, we successfully used this restraining method on the gecko *Nephrurus amyae* without any damage to its delicate "knob-tail." This method ensures that lizards are only held for a short period of time, therefore reducing prolonged stress, which can result in tail autotomy.

Our technique is inexpensive and allows efficient data collection in the field or laboratory. The design of the tray allows lizards to be positioned for a number of purposes including taking morphological and color measurements, photographs, or tissue samples.

Acknowledgments.—We thank J. Van Buskirk for his advice and assistance, J. Sinclair, the Live Exhibits staff at Museum Victoria, and two anonymous reviewers. Permits were provided by the Department of Sustainability and Environment Victoria and the Department for Environment and Heritage South Australia (Permit Nos. 10002952 and E24870, respectively). Funding was provided by an Australian Research Council Discovery Grant (DP0452082) and an Australian Society of Herpetologists Student Research Grant. This research was approved by The University of Melbourne Faculty of Science Animal Experimental Ethics Committee and The South Australian Wildlife Ethics Committee.

HERPETOLOGICAL REVIEW

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2006 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

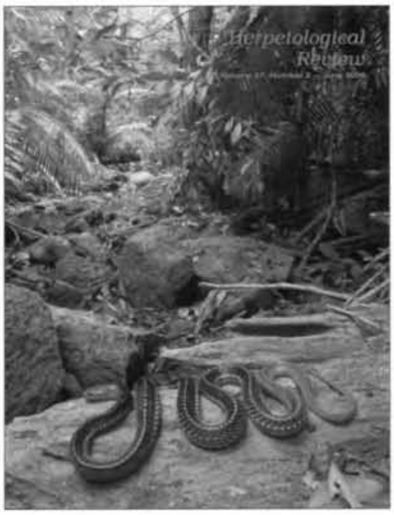
All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with VISA or MasterCard (account number and expiration date must be provided). Payment should be sent to: Breck Bartholomew, SSAR Membership Office, P.O. Box 58517, Salt Lake City, Utah 84158, USA. Fax: (801) 453-0489; e-mail: ssar@herplit.com.

Future Annual Meetings

2006 — New Orleans, Louisiana, 12–17 July (with ASIH, HL)
2007 — Saint Louis, Missouri (with ASIH, HL)

About Our Cover: *Bungarus flaviceps*



The Red- (or Yellow-) headed Krait (*Bungarus flaviceps*) is one of the rarest species of *Bungarus* despite its extensive distribution which extends throughout Indochina and south through peninsular Thailand and Malaysia to Singapore and onto the islands of Sumatra and Borneo. Snakes are found in both lowland and hilly forested areas, and in peninsular Malaysia, seem to be associated with small watercourses provided that suitable cover is nearby. Adult *B. flaviceps* can reach nearly 2 m in length, and given the toxicity of their venom, this makes them quite dangerous. Although secretive and shy by nature, *B. flaviceps* can become extremely aggressive, quick, and agile when cornered and photographing this species can be rather nerve wracking. Like most elapids, *B. flaviceps* feeds on other reptiles, principally snakes and skinks. The foregoing is drawn largely from Manthey and Grossmann (1997. Amphibien & Reptilien Südostasiens. Natur und Tier Verlag, Müster. 512 pp.) and Stuebing and Inger (1999. A Field Guide to the Snakes of Borneo. Natural History Publications, Kota Kinabalu, Borneo. 254 pp.).

The specimen illustrated on the cover is the first *Bungarus flaviceps* to be collected from Pulau Tioman, although reports of an early specimen exist (van Rooijen 2001. Lacerta 59:97–103). Pulau Tioman is a relatively small, landbridge island located 29 km off the southeastern coast of peninsular Malaysia in the South China Sea. Pulau Tioman is just one of 62 islands in the Seribuat Archipelago (Grismer 2006. A Field Guide to the Amphibians and Reptiles of the Tioman Archipelago, Malaysia. Forestry Department, Peninsular Malaysia) and harbors at least 98 species of which 17% are endemic (see Grismer et al. 2006. Raffles Bulletin of Zoology 54:157–180 and references therein). The high herpetofaunal diversity of Tioman Island is supported by the extreme environmental diversity of its pristine habitats ranging from mangrove swamps along the coast to lowland and hill dipterocarp rainforests inland.

The cover specimen was collected at night along the Mentawak River on the eastern side of the island as it was moving across the leaf litter of the forest floor. It was placed in position the next day at the top of the Tekek-Juara trail and photographed using a Nikon D100 with a 20 mm lens at an ISO equivalent of 200. The photographer, **Lee Grismer**, is Professor of Biology at La Sierra University in southern California. Grismer's fieldwork since 2000 has been centered in Malaysia, but has recently expanded into Cambodia and will move into southern Vietnam this summer. He is currently working on a mongraphic revision of the lizards of peninsular Malaysia, Singapore, and associated islands. Much of this work involves collaborations with Malaysian scientists and students from Universiti Kebangsaan Malaysia (National University of Malaysia).

SSAR BUSINESS

SSAR Herp Hotline is Up and Running

The new SSAR Herpetology Education Committee has activated an on-line questionnaire form to facilitate communication and education between the public and professionals. The hotline also frees the presidents of our societies, who historically took responsibility for answering many letters, phone calls, and emails from enthusiasts. Just since January, over 70 questions on many topics, including specimen identification and husbandry for pets, have been posted and answered, primarily by herpetologists at Zoo Atlanta. We're especially grateful to Dr. Brad Lock (Zoo Atlanta) for his contributions. Gregory Watkins-Colwell of the Yale Peabody Museum of Natural History and Joseph Mendelson of Zoo Atlanta have worked together to design and implement this important interface. We also hope that professionals and experts in academia will participate by posting questions and serving as authorities in answering queries on specific topics. The form is currently accessible from the SSAR web page. Check it out!

http://www.peabody.yale.edu/collections/vz/herpform.html

Dean E. Metter Memorial Award 2006

The Dean E. Metter Memorial Award was established to encourage students to pursue field research in herpetology and to facilitate field research by providing funds for related expenses. The Metter Memorial Award Committee is pleased to announce that this year's winner is Ms. Cybil Nichole Smith, whose project is titled: "The Significance of the Distinctive Color Pattern and Behavior of Hatchling Great Plains Skinks (*Eumeces obsoletus*)." Ten proposals were submitted this year and the committee (Joe Beatty, Anne Maglia, and Brian Miller) was impressed with all, but had to choose a single awardee.

Nikki Smith graduated with honors from Oklahoma State University in May 2006 with a B.S. in Wildlife and Fisheries Ecology (emphasis in Wildlife Management). Since 2003, she has worked in the laboratory of Dr. Stanley F. Fox, who will serve as her advisor and mentor for this project. She has also participated in several other research projects while completing her degree that involved both laboratory and field work. Ms. Smith is the first undergraduate to win the Metter Memorial Award.

Her proposal will address the significance of the phenotypic (color and behavior) differences between juvenile and adult *Eumeces obsoletus*. She has designed a series of experiments to test whether or not the Giant Whipscorpion (Vinegaroon), (*Mastigoproctus giganteus*), might be a noxious model for the juvenile phenotype of *E. obsoletus*.

NEWSNOTES

A. Stanley Rand Fellowship Established

In recognition of Stan Rand's efforts to foster and promote the careers of Latin American biologists and his belief in the importance and value of organism-driven, field-based tropical research, the Smithsonian Tropical Research Institute has established an A. Stanley Rand Fellowship, to be awarded preferentially to a Latin American student who is studying animal behavior or ecology. This Fellowship fund, which has already grown to almost US $15,000, will honor Stan's memory and lifetime scientific achievements.

Contributions or inquiries may be sent to: Lisa Barnett, Smithsonian Tropical Research Institute, 1100 Jefferson Drive, Suite 3123, MRC-705, Washington, DC 20013-7012, USA.

Canadian Association of Herpetologists

The Canadian Association of Herpetologists publishes *The CAH/ACH BULLETIN* twice each year. The BULLETIN will print articles and news of interest to herpetologists in Canada. These may be in the form of short announcements or letters, or may be written as longer articles (non-peer reviewed). The BULLETIN especially requests news of your research lab and current research activities, lists of your latest publications (up to one year old), travel plans, new students, grants, awards, fellowships, new books or book reviews, trivia or concerns. Please send your submissions to the Editor (Jackie Litzgus, jlitzgus@laurentian.ca) as an MS Word document attached to an email.

You can receive a free copy of the latest issue of the *CAH/ACH BULLETIN* by emailing Jackie (jlitzgus@laurentian.ca) with a request. Please distribute the *BULLETIN* widely to all those that you may think would be interested in participating in the CAH/ACH. The last page of the BULLETIN is a CAH/ACH membership form—please join us!

Extinction is Imminent for the Guatemalan Beaded Lizard (*Heloderma horridum charlesbogerti*)

The Guatemalan Beaded Lizard is endemic to the arid, desert region of the Motagua valley in southeastern Guatemala and is one of the most endangered animals in the world. This animal was first seen by scientists in 1984, formally described in 1988 and a decade later was thought to be extinct in the wild. In 2002, a few individuals were found and limited natural history and ecology studies resulted in the first, but sparse, data on their lives in the wild. Most aspects of the lives of these creatures remain a mystery. The Department of Herpetology at Zoo Atlanta is working closely with the Guatemalan organization ZooTropic to create a conservation plan for these lizards.

What Happened?

What were the some of the factors that have led to the decline of the Guatemalan Beaded Lizard? First, beaded lizards live only in a tiny sliver of isolated desert habitat in the Motagua Valley of Guatemala; this area is isolated by massive cloud-forested mountains and rainforest valleys. Thus, it seems these Guatemalan lizards have had an historically limited range and have evidently existed in total isolation on this tiny island of desert habitat for many thousands of years. Further, land conversion for cantaloupe, tobacco, and corn farming has reduced the suitable habitat for this lizard to about 40,000 acres (roughly the size of Disney World in Orlando); best estimates have it that this area could support only 150–200 individuals. These numbers are similar to some of the most endangered island iguanas. Being a venomous creature has not helped this lizard; many negative myths and attitudes surround this animal. For example, it is thought by the local inhabitants, that if your shadow crosses or touches a lizard you will begin to slowly waste away and eventually die. Due to these myths, until recently, lizards have been killed on sight. Lastly, the rarity of this subspecies in particular and the popularity of beaded lizards and gila monsters as captives in general has led to exploitation for the animal collection market. It has been estimated that approximately 35 individuals were captured and sold abroad during the decade of the 1990s.

Is There Any Hope?

Because of the recent re-discovery of the species and the two natural history studies performed with support of Zootropic, the government of Guatemala has shown interest in protecting this animal and its habitat. In addition, Zootropic has launched an education campaign working with villagers in the Motagua region. This program has already visited over 25,000 children and adults and, since 2004, there have been no reports of lizards being killed or sold. Studies are planned to answer basic questions concerning critical habitat needs. These will be the main data needed to guide land-preservation decisions to best help this creature. There are also about nine animals in captivity in Guatemala, spread among as many institutions. A breeding facility in the Motagua Valley is urgently needed to produce young animals for attempted reintroduction (and education) programs in protected areas.

How You Can Help

As stated, there are likely no more than 200 individual Guatemalan Beaded Lizards left on Earth. Your help is desperately needed to save these unique creatures. Wayne Hill and the 2006 National Reptile Breeder's Expo have agreed to support the conservation effort for the Guatemalan Beaded Lizard. All proceeds from this year's annual auction will go to the "Project Heloderma" fund. This is hugely important, and we thank Wayne for his generous support of this project. To make this auction a success we request auction items of any sort. Monies collected for this fund will only go to efforts to save the Guatemalan Beaded Lizard. This fund will be specifically used to fund conservation research projects, raise public awareness in Guatemala, and establish a critically needed in-country breeding and conservation facility. Auction items should be sent so as to arrive by the first week in August. For more information on the auction please visit www.IRCF.org/Project Heloderma.

If you would like to help by contributing auction items please send these to:

Wayne Hill
621 Avenue M S.W.
Winter Haven, Florida 33880, USA
Attn: Project Heloderma

Please e-mail a description and value of potential auction items to: Dr. Brad Lock, Assistant Curator of Herpetology, Zoo Atlanta (e-mail: block@zooatlanta.org).

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

12–17 July 2006—49th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. New Orleans, Louisiana, USA. Information: http://www.dce.ksu/jointmeeting/.

10–13 August 2006—Turtle Survival Alliance, Fourth Annual Conference, St. Louis Zoo, St. Louis, Missouri, USA. Joint meeting with IUCN Tortoise and Freshwater Turtle Specialist Group. Information: http://turtlesurvival.org/.

6–9 November 2006—9th Reunión Nacional de Herpetología México, hosted by the Mexican Herpetological Society. Universidad Autónoma de Nuevo León, Monterrey, Nuevo León, México. Information: http://www.sociedadherpetologicamexicana.com/.

24–27 November 2006—Herpetological Association of Africa 8th Conference. Potchefstroom campus of the North-West University, South Africa. Information available from the conference website: www.wits.ac.za/haa/2006conf.htm.

16–20 April 2007—First Mediterranean Herpetological Congress, Marrakech, Morocco. Information available from the Congress website: www.ucam.ac.ma/cmh1.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **María del Rosario Castañeda** or **Michele Johnson**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Biogeography of West Indian Ocean *Cryptoblepharus* Lizards: An Example of Transoceanic Dispersal

The genus *Cryptoblepharus* is composed of ~36 morphologically similar forms considered to be subspecies within a single species, *C. boutonii*. The geographic distribution of the group includes the Indo-Pacific, Australian, and Malagasy regions. According to biogeographical theory, three different scenarios could result in this disjunct distribution: 1) evolution of the ancestral form at a time when the landmasses were connected, 2) natural long-distance transoceanic dispersal over a long period of time, and 3) recent human-mediated transportation. The authors used mitochondrial DNA (12S and 16S fragments) to reconstruct phylogenetic relationships between *Cryptoblepharus* subspecies of the Western Indian Ocean region, test alternative mechanisms to explain the present geographic distribution and evaluate the current taxonomic status. The previously estimated age of the group and the low genetic divergences found between Indo-Pacific/Australian and Malagasy sequences reject the ancient vicariance hypothesis. In addition, the geographically structured genetic variation observed rejects the recent human-mediated transportation hypothesis, supporting by process of elimination the transoceanic dispersal scenario as the origin of the Western Indian Ocean *Cryptoblepharus*. The authors also found that morphological variation (especially distinct coloration patterns) is not always concordant with molecular variation, as some of the morphologically distinct forms share or have closely related haplotypes, and considerable genetic variation is found in morphologically undistinguishable forms. Based on these findings the authors propose the maintenance of the subspecific status of all the forms as the most appropriate taxonomic arrangement for the group.

Rocha, S., M. A. Carretero, M. Vences, F. Glaw, and D. J. Harris. 2006. Deciphering patterns of transoceanic dispersal: the evolutionary origin and biogeography of coastal lizards (*Cryptoblepharus*) in the Western Indian Ocean region. Journal of Biogeography 33:13–22.

Asynchronous Eye Closure as an Antipredator Strategy in *Sceloporus* Lizards

Sleeping is a behavioral state in which an animal is highly vulnerable to predation. Some animals have developed mechanisms to reconcile the need to be vigilant and the need to sleep. Keeping one eye open while the other is closed, called asynchronous eye closure (ASEC), is a behavior associated with unihemispheric sleep (in birds and aquatic mammals), where the hemisphere opposite to the closed eye sleeps while the other hemisphere remains awake with its associated eye open and functional. In birds ASEC has been suggested to be an important antipredatory strategy; however, this association is poorly studied in other animals. The au-

thors studied ASEC behavior in the Western Fence Lizard *Sceloporus occidentalis*. Three different eye states were specified: both eyes open (synchronous eye opening, SEO), one eye open and the other closed (asynchronous eye closure, ASEC), and both eyes closed (synchronous eye closure, SEC). Using video recordings, the authors determined the eye state of the subjects under three different treatments: 1) an empty control, where the lizard was alone in a terrarium, 2) a movement control, where the lizard was presented with a moving object, and 3) the predator treatment, where the lizard was presented with a living snake. The authors also determined the orientation of the open eye during the ASEC state. Results support the predictions based on the anti-predator hypothesis: visual scanning increased in the presence of a possible predator (due to an increase of ASEC and a reduction of SEC, with SEO remaining invariable) and the opened eye was directed towards the threat. The authors also discuss alternative hypotheses of the purpose of ASEC considering their findings.

MATHEWS, C. G., J. A. LESKU, S. L. LIMA, AND C. J. AMLANER. 2006. Asynchronous eye closure as an anti-predator behavior in the Western fence lizard (*Sceloporus occidentalis*). Ethology 112:286–292.

Ultrasonic Communication in Frogs

The authors report evidence of ultrasonic communication in the Concave-eared Torrent Frog *Amolops tormotus* from Huangshan Hot Springs in China. Experiments to detect communication included acoustic playbacks in the frog's natural environment with 1) the ultrasonic component of the call only, and 2) the audible component of the call only. Five out of eight experimental male subjects responded to the ultrasound signal with an increase in the calling rate. Additionally, to detect ultrasonic sensitivity in *A. tormotus*, electrophysiological recordings from the torus semicircularis (the portion of the midbrain where auditory processing occurs) were used. Both auditory-evoked potentials (AEPs) and tone-burst responses revealed high ultrasonic sensitivity. Based on the acoustic spectrum of the background noise of *A. tormotus* environment, the authors suggested that ultrasonic sensitivity is probably an adaptation to prevent the masking of the calling by background noise. Two additional species were tested for ultrasonic sensitivity: *Odorrana livida*, which also inhabits Huangshan Hot Springs, and *Pelophylax nigromaculata*, which is common in rice fields. The former showed the ability to detect ultrasound, but the latter showed a limited upper hearing limit, supporting the association between noisy environments and ultrasonic hearing. Furthermore, to determine if ultrasound detection in *A. tormotus* occurs by ear stimulation via bone conduction, the authors recorded the sound reception of the midbrain with the subjects' ears unobstructed or obstructed with clay; results indicate that ultrasonic sensitivity is mediated by acoustic stimulation of the ear. Finally, the authors report unusual morphological features found only in the ear of *A. tormotus* males, which might help explain the capacity to detect ultrasound. However, further experiments are required to test if females could also detect ultrasound or if the ultrasonic hearing in *A. tormotus* is sexually dimorphic.

FENG, A. S., P. M. NARINS, C. H. XU, W. Y. LIN, Z. L. YU, Q. QIU, Z. M. XU, AND J. X. SHEN. 2006. Ultrasonic communication in frogs. Nature 440:333–336.

Prey Size and Phenotypic Plasticity in *Boa* Snakes

Diet studies in vertebrates have shown that type and size of food items could have a significant effect on morphological phenotypic plasticity. The authors manipulated the diet of *Boa constrictor* juveniles to test whether prey size induces skull and jaw phenotypic plasticity early in ontogeny. Additionally, they studied the specific timing of expression of sexual size dimorphism (SSD; in *B. constrictor* adult females are significantly larger than adult males). Twenty-three neonates from a single-sired litter (reducing the effects of parental genetic variation) were maintained under two different diet regimens: 1) small-prey (mice), and 2) large-prey (rats) items. Individuals in both treatments received equivalent prey mass: the small-prey treatment was fed a larger number of smaller prey, while the large-prey treatment was fed a smaller number of larger prey. Morphological measurements were taken twice during the experiment, at 5 and 58 weeks, and included the premaxilla–basioccipital length and mandible length (using x-rays), snout–vent length, body length, tail length, and body mass. No statistical difference was found in the premaxilla–basioccipital length or mandible length between the two treatments, rejecting the hypothesis that large prey induces phenotypic plasticity of head elements early in ontogeny in *B. constrictor.* However, at 1-year of age, SSD was found in snout–vent length and body length (females > males) and tail length (males > females), suggesting a strong genetic component early in ontogeny in the SSD, independent from environmental factors (e.g., prey mass consumed). Finally, the authors comment on future directions of the study of ontogenetic growth and SSD expression.

SCHUETT, G. W., D. L. HARDY SR., R. L. EARLEY, AND H. W. GREENE. 2005. Does prey size induce head skeleton phenotypic plasticity during early ontogeny in the snake *Boa constrictor*? Journal of Zoology 267:363–369.

Tempo and Mode of Diversification in *Plethodon* Salamanders: A Non-Adaptive Radiation Case

Clades that exhibit rapid divergence into a wide variety of adaptively dissimilar forms, called adaptive radiations, have been model systems to quantify rates of diversification. However, few studies have quantified the tempo of diversification in species-rich clades that have negligible adaptive disparity (non-adaptive radiations). *Plethodon* salamanders form a specious clade that exhibits extreme morphological stasis. Using mitochondrial DNA, the authors 1) reconstructed the phylogeny of eastern North Ameri-

can species (44 spp), 2) estimated diversification rates using the constant rate (CR) test (which tests for a significant departure from the null hypothesis of a constant rate of diversification), and 3) tested three alternative models for lineage accumulation using the program Diversi v.0.20. Additionally, the authors tested the effects of possible missing lineages on the diversification rates estimations, and the assumption of equal probability of speciation and extinction among lineages. Results indicate that major *Plethodon* clades exhibit significant differences in rates of lineage accumulation, and even within major clades the lineage accumulation has not been constant throughout its phylogenetic history. Southern clades showed higher lineage diversification than northern clades, which the authors suggested is related to areas unsuitable for occupation during Pleistocene glacial maxima. Furthermore, the authors point out that diversification rates of *Plethodon* are comparable with those classical examples of adaptive radiation, and that the temporal depth of this group is also notable since there has been a longer time for extinction, comparing with more recent adaptive radiation examples. The authors finally discuss characteristics of the evolutionary history and probable causes of the particularly high rates of diversification within *Plethodon*.

Forest Fragmentation Effects on *Phyllomedusa* Reproductive Dynamics

In the late 1970's and early 1980's a project was created to study fragmentation effects in Brazil, the Biological Dynamics of Forest Fragments Project (BDFFP), which consisted of a series of forest patches of 1, 10 or 100 ha, surrounded by a matrix of pasture and regenerating vegetation areas. In this fragmented landscape, the authors studied the reproductive dynamics of *Phyllomedusa tarsius*, a hylid frog that breeds in ponds located in continuous forest, as well as highly disturbed habitats. Body size, abundance, and movement patterns were measured/estimated in five different habitats: 1) pasture, 2) *Vismia* spp. regrowth (areas that have been cleared and burned), 3) *Cecropia* spp. regrowth (areas that have been cleared but not burned), 4) small forest fragments (1–10 ha), and 5) continuous forest. Reproductive ponds were visited during three consecutive years, and capture-mark-recapture techniques were implemented. The authors found differences between habitats in number of frogs per pond (*Cecropia* spp. regrowth had the highest number) and pond area. They also found that the beginning of the reproductive season varied among habitats, initiating in November in continuous forest and in January in disturbed habitats. Rainfall was positively correlated and significant with number of captures in pastures, and *Vismia* and *Cecropia* patches. Movement patterns of frogs differed between habitats: *Vismia* spp. regrowth, pastures, and forest fragments had the highest proportion of male movements. No movements from disturbed habitats into the continuous forest were recorded, even though the longest journey observed was longer than the distance between forest and secondary growth ponds, suggesting that interbreeding between habitats is possible, though is not occurring. The authors highlight the importance of studies that identify factors responsible for persistence of populations in different habitats as a base to design areas for biodiversity conservation.

Negative Effects of Natural Disturbances Disruption in Salamanders

Human disturbances in native habitats have been associated with creating suitable conditions for invasive species establishment, contributing with the decline of local species. One type of human alteration results from changing the intensity and/or frequency of natural disturbances. In the San Rafael Valley, Arizona, cattle farmers have replaced seasonal marshes with artificial ponds to maintain water available all year round. The Sonoran tiger salamander, *Ambystoma tigrinum stebbinsi*, a recently listed endangered species whose range is restricted primarily to the San Rafael Valley, now breeds in the artificial ponds. These ponds have been invaded by bullfrogs (*Rana catesbeiana*) and several species of fishes that otherwise would not survive in the area due to their high susceptibility to pond drying. The authors hypothesized that reduction in the natural drying frequency of the aquatic habitats has led to the invasion by bullfrogs and fishes, and that these species exclude native salamanders. Data was collected from 1979 through 1999; pond-drying frequency, permanence, and new colonization or reappearance of bullfrogs, fishes and salamanders were estimated. In addition, the effects of a range of drying frequencies on the distribution of fish, bullfrogs and salamanders were estimated using a variation of the Levin's (1969) metapopulation model. Results show that after pond drying both bullfrog and fish populations disappeared; salamander populations were also affected by drying, but to a lesser extent. Salamanders were more likely to recolonize a pond following drying, i.e. when fish and bullfrog populations were eliminated, and once salamanders were eliminated from a pond the population rarely reappeared unless fishes were eliminated. The mathematical model predicted a community dominated by fishes and bullfrogs when pond drying was infrequent, but an increase drying frequency would also be detrimental for salamanders because it would restrict breeding. These results suggest that an adequate management of disturbance regimes is an important tool in controlling invasive species.

Population Structure of *Podocnemis expansa* in a Conservation Context

Podocnemis expansa, the giant Amazon River turtle, is distributed in the Amazon, Orinoco and Esequibo river basins east of the Andes. Once widely common in the area, this species has been the subject of intense poaching for meat and eggs, given their large size, high fecundity and gregarious nesting. The authors evaluated broad-scale patterns of population genetic variation, and estimated the extent of population declines and their effects on the loss of genetic diversity. Data included sequences from the complete mitochondrial control region and nine nuclear microsatellite markers from eighteen localities, for a total of 453 samples. Several analytical methods were implemented including equilibrium and nonequilibrium population genetic methods to account for possible model assumption violations given nonequilibrium conditions expected in declining or expanding populations. Results show concordance between datasets and methods. Population structure reflects a pattern characterized by limited dispersal among sub-basins and high gene flow among populations within a sub-basin. Populations within sub-basins appear to be panmictic, and there is a lack of natal homing to individual nesting beaches; however, a natal-river fidelity that maintains differentiation between rivers seem to exist, even when geographically close. Large differences in haplotype and allele frequencies, as well as microsatellite data are consistent with the observation that population size has been extensively reduced due to hunting over the past two centuries. The authors discuss the conservation implications of their results for the genetic management of this species.

Morphological Changes After Colonization in the Invasive Species *Bufo marinus*

After colonization, invasive species are expected to suffer a reduction in their genetic variability as a result of strong founder effects. However, many invasive species show phenotypic lability as a response to new environments. Understanding the phenotypic changes that invasive species undergo after colonization might also help understanding the long-term effects of the colonization itself. The cane toad, *Bufo marinus*, is a very successful and highly toxic invader that affects native terrestrial predators that are naïve to their toxicity and die trying to consume them. The authors studied changes in body size and parotoid gland size (as an index of toxicity level) of *B. marinus* with respect to time of colonization in Australia. Body size (snout–ischium length) and parotoid size (length and width) of museum specimens, in addition to climatic factors including temperature, precipitation, and humidity, were analyzed with multiple regression and a model selection approach. Time since colonization was estimated in ARCVIEW using linear interpolation of locality and date of collection data from specimens. Results show a significant effect of climate, latitude and time since colonization on toad morphology. Time since colonization appears to be associated with reduction in body size and parotoid gland size, however, in areas of higher rainfall, the effects appear to be reduced or reversed. The authors suggest this change in morphology could be related with the detrimental effect of toads on the quality of the environment (e.g., reducing food resources), causing the attainment of large size more difficult or as an adaptive change to the new environment, where large body sizes or higher toxicity grants little or no selective advantage. Fortunately, results indicate that *B. marinus* impact over native predators is maximal at first arrival and decreases over time.

PHILLIPS, B. L., AND R. SHINE. 2005. The morphology, and hence impact, of an invasive species (the cane toad, *Bufo marinus*): changes with time since colonization. Animal Conservation 8:407–413.

OBITUARIES

Herpetological Review, 2006, 37(2), 134–137.

A. Stanley Rand (1932–2005)

MICHAEL J. RYAN
Section of Integrative Biology, 1 University Station C0930
University of Texas, Austin, Texas 78712—0253, USA
e-mail: mryan@mail.utexas.edu

There is a hole in my chest where my heart used to be, and a chasm in tropical biology the size of the Panama Canal. Stan Rand died on November 14, 2005 and we are all the worse off for it, personally and professionally.

Stan Rand at the World Congress of Herpetology in Prague, 1997.

Dr. Austin Stanley Rand, Stan to all who knew him, was born on September 29, 1932. Perhaps destiny dealt him no choice but greatness in biology, as his father Austin was already a famous

ornithologist at Stan's birth. Stan was never far from field biology or museums when he grew up— he published his first paper when he was 12!

Stan began his graduate studies with Dr. Ernest Williams at Harvard, where he became an early member of that awesome lineage of students of *Anolis* biology under Williams' tutelage. He received his Ph.D. in 1961, and remained at Harvard on a postdoc for one year which included an intensive period of study of Jamaican anoles at the University of the West Indies. He and his wife Pat then relocated in Sao Paulo, Brazil, for two years while Stan was a postdoc with Dr. Paulo Vanzolini. Initially, Stan was paid from royalties from a song that "Vanzo" wrote which must have been quite a hit in Brazil—maybe, Stan always lived modestly and money was never a big issue to him. Regardless, the Rand's first child, Hugh, was born there and it appears he didn't starve.

In 1964 Stan received an invitation from Dr. Martin Moynihan to join a new cadre of impressive young scientists that Moynihan was assembling at the Smithsonian Tropical Research Institute in Panama. Stan joined the staff. He, Pat, and Hugh moved to Panama and had two daughters, Margaret and Katherine, on STRI's Barro Colorado Island (BCI), where the forest was inhabited by anoles and iguanas during the day and the Rands were serenaded by choruses of túngara frogs at night.

Stan published early and often— over 100 scientific papers in 60 years of publishing. (Note that he is not done yet. Túngara Frog papers with his data will continue to bare his name for some time, and I predict there will be one in 2014 which will mark Stan's 70th year in the scientific literature.) Much of Stan's scientific contributions can be partitioned into studies of *Anolis* lizards, iguanas and crocodiles, and, as a grand finale, his study of Túngara Frogs. Stan explored many fascinating tidbits of nature in between these projects but I will briefly review only these contributions here.

Stan published a series of studies on *Anolis* biology in the 1960s that had an immediate and lasting impact on tropical biology, ecology, and behavioral ecology. Prominent among those contributions was his notion of the "ecomorph." The genesis of this concept originated with his data showing that on each island of the Greater Antilles, different *Anolis* species had diversified and adapted to nearly identical niches among islands. During that time Stan also investigated dominance interactions among lizards, showing that if the size difference between males was sufficient, the larger male won, but if there were a smaller size difference the resident won. He demonstrated the "residency effect" in 1967, well before this became an important issue in behavioral ecology. Stan also integrated physiological ecology into his studies. Critical to the concept of the ecomorph was the climatic, not just the structural, habitat the lizards occupied. At the behavioral level he showed that lizards' response to predators was strongly influenced by their body temperature. All of this foreshadowed Stan's continuing emphasis on the organism's entire biology and the necessity of viewing in its natural context.

Stan made at least two other major contributions from his work with *Anolis*. One was a paper with Williams in 1970 on signal redundancy in communication systems. They used information theory to estimate the quantity of information about species identity that could potentially be communicated in a lizard community. They calculated that the total amount far exceeded what was necessary. This study was a wonderful demonstration of how animals use multiple aspects of their displays to reinforce the same message, and it was one of the first uses of information theory applied to animal communication in the wild. Stan also considered the relationship between ecological space and predator-prey interactions in the context of "aspect diversity," arguing that variation among species could result from predator-driven selection that causes species to diverge in the "escape space" available to them. This concept greatly augmented studies of apostatic selection and anticipated much of the work we see today in sensory ecology. (Thanks to both Ray Huey and Jonathon Losos for their thoughts on Stan's *Anolis* work.)

Another stage in Stan's work dealt with social behavior in and between green iguanas and crocodiles. Much of this work was with Gordon Burghardt and his students, centered on the small island of Slothia, a mere stone's thrown from Barro Colorado Island. Female iguanas swim to Slothia from BCI and communally nest. Stan and his brother Will wrote an insightful paper on conflict resolution. It analyzed the competition between female iguanas over burrows they dug for nesting. The analysis combined stochastic processes and energetic constraints and showed that females took into consideration the amount of energy they had expended in building the burrow. This study later lead to some consternation among theoreticians interested in honest signals who were convinced that the "Concorde Effect" (adding more investment only because past investments have been made) should be maladaptive. I remember one night on BCI when, over some rather mediocre Panamanian rum, John Maynard Smith (who to me was always the "Stan of theoretical biology"), asking Stan just how this could be. Although Stan knew the theory about games, the data reined supreme— this is what they do, he replied.

There were also some interesting interactions between crocs and the female iguanas that few besides Stan had witnessed. A female croc had earlier nested at the same site where the fecund iguanas sought shelter for their eggs. The female croc, Natasha as the several meter crocodile was affectionately known, rushed a nesting iguana, and grabbed the expectant mother in her mouth. Instead of devouring her, or at least dismembering her as any protective maternal archosaur should do, Natasha delicately carried the iguana back to the water and released her. Crocodiles carry their newly hatched young to the water, so Stan thought that having a small squirming baby reptile in her mouth released Natasha's maternal instincts. Some of this crocodile work is published, and much more is oral history on BCI. When great scientists such as Stan pass, we marvel at the accumulation of knowledge they left us, and we lament the untapped knowledge that went with them.

Stan began to study acoustic communication in frogs in the forest of Boracéia in Brazil while conducting his postdoctoral research with Vanzolini. That interest continued when he moved to Panama. He immediately set out to document the vocal diversity of these gnomes of the Panamanian nights, but he also turned his considerable nocturnal skills towards one species, the túngara frog, *Physalaemus pustulosus*, which then had the more melodious moniker of *Engystomops*.

I went to BCI to begin my studies of sexual selection and communication in red-eyed tree frogs in 1978. These frogs proved intractable for the study I had planned, and I quickly switched my attention to túngara frogs. At this point Stan had published one paper on their foam-nesting behavior, although nothing on their

communication. But he gave me a manuscript that had been written in the late 1960's or early 1970's. It described the complex calling of these frogs, a simple call, or "whine," that could be produced alone or could be followed by one-to-many secondary components, or "chucks". The manuscript was filled with incredibly interesting and detailed natural history as well as experimental studies of female phonotaxis. Among other things, Stan was interested in whether female frogs were more attracted to the complex call over the simple call. These experiments were conducted when the emphasis of mate recognition was focused at the species level and was concerned with how it contributed to speciation through behavioral isolation. In frogs this work was being carried out in exemplary fashion by such luminaries as Murray Littlejohn and Carl Gerhardt both of whom were inspired by the earlier studies of Frank Blair. So at that time, Stan was working in the intellectual shadow of the Modern Synthesis and its emphasis on speciation, but instead he was addressing questions about female choice and sexual selection. This was some time before Robert Trivers (who also worked on *Anolis* and was advised by Williams during his Ph.D. thesis) wrote his paper on parental investment and sexual selection in 1972. I added some to that early manuscript of Stan's and we published it in 1981. I finished my thesis in 1982 while Stan was still concentrating on reptiles.

Stan and I remained in touch during the next few years while neither of us worked on these frogs. In 1985 we met in the halls of the Smithsonian's Natural History Museum in Washington D.C. and I asked, why don't we start up a joint project with those little beasts. In 1986 we began a now 20-year collaboration on what became known to some as the "túngara frog project". Our initial interests were modest as we began testing female phonotaxis in a car port using a plywood and burlap testing chamber in Gamboa, Panama. Stan and family had just moved from Panama City to Gamboa, and STRI was figuring to have some laboratory facilities there soon. The first question we addressed was what aspects of the mating call made it attractive to females, and the first studies we published in 1990 argued that in this system sexual selection was generated by sensory exploitation. That idea, convergent with and inspired by others such as MJ West Eberhard at STRI, has generated some interest. Our interests in sexual communication in these frogs continued to expand in concert with the lab facilities in Gamboa, which in turn accommodated a more sophisticated approach to our own research questions.

Stan was always interested in the entire biology of the animal and our studies soon grew to embrace additional aspects of communication, comparative studies of populations and related species and, through our collaboration with Dr. Walt Wilczysnki, the neural mechanisms that controlled mate choice. Memorable during those years was a 5000 km transect that Stan and I sampled in which we collected túngara frog calls and tissues throughout the entire range of this species. Most of the data were collected when we departed from Austin, Texas after the meetings of the American Society of Ichthyologist and Herpetologist (ASIH) that was hosted there in 1993. We drove from Texas to Panama collecting all the way. Those samples were supplemented by numerous trips to South America, where we studied other populations of túngara frogs and their relatives. The data from that transect has provided the grist for at least four separate studies, and its uses are still not exhausted.

In the year 2000, Stan, Walt Wilczynski, David Cannatella and I were PI's on a multidisciplinary grant. This grant, which involved collaborations among more than half-a-dozen labs, addressed issues from phylogenetics to molecular neurobiology, all emanating from the basic biology of the túngara frog that Stan first glimpsed in 1964. As the grant ended in 2004 we were asked to organize a two-day symposium on "Sexual Communication in Túngara Frogs" at the Animal Behavior Society meetings in Oaxaca, Mexico. To kick off this symposium numerous attendees, many with little or no interest in frogs, sexual selection, or communication per se, packed the room to hear Stan Rand present what ended up being his last scientific presentation—"Natural History of the Túngara Frog". When Stan finished that talk, there was a sustained applause in which I detected a tone of reverence and appreciation for someone special.

The work on túngara frogs will continue unabated, it will be a scientific legacy to Stan, but more so. It will be a continuing collaboration from the grave. Although no longer with us, we will never outlive Stan's inspiration nor exhaust his insights.

Having now provided a most cursory summary of Dr. Rand's scientific career, I would like to end saying more about Stan as the person; this is the real reason why so many of us mourn his passing

Above all Stan was a naturalist. His eyes, ears, and mind were focused on the organism in its environment. He was well schooled in theory but not terribly impressed by it. He was a great experimenter, but was always a bit cynical about how such results might apply in the wild. An anecdote. We were waiting out a drought in a small dusty town in the bush in Brazil. We went to see a movie, "Edward Scissorhands". An old woman narrates the story in which as a youth she befriends a boy who has scissors for hands. Afterwards, I asked Stan how he liked the movie. He said it was totally unrealistic, the chronology didn't match, the old woman could not have been a youngster when she first met Edward S. I said "Stan, for chris-sakes, the boy had scissors for hands! How realistic is that. So what if the chronology was off". He wouldn't budge. The opening of the movie was built on a house of cards and he could contemplate no further.

For most Stan is intricately associated with STRI. The Smithsonian Tropical Research Institute is a great institution, and Barro Colorado Island is its crown jewel. We celebrated Stan's retirement from STRI with a symposium in his honor at the 1998 meetings of the ASIH in Guelph, Canada, the proceedings of which are published in "Anuran Communication" (Smithsonian Institution Press, Washington DC, 2001). All of the more than 20 authors I first invited to participate said yes—so much for a back up list! When I introduced the symposium I said that but perhaps for BCI, Stan was STRI's most valuable resource. An institution's greatness is defined, of course, not just by its physical facilities but by its humanity. And it is here that Stan made by far his greatest contribution. Because of his immense knowledge of tropical biology, Stan was often called upon for advice, especially to initiate novices to this land of plenty. His generosity knew no bounds, and his humor, warmth and enthusiasm were contagious. He readily extended this generosity into the personal realm. He and Pat were the social hub of Gamboa for the last 20 years and their house a scientific salon. Pat's famous "frog dinners" for many of the visiting researchers in Gamboa (regardless of whether or not the sci-

entists worked on frogs) were the social highlight of our summer. These dinners were also an incubator of scientific ideas. Stan was not a "science nerd," he was broadly informed and could entertainingly engage one with a broad array of topics, but his insights and wit were always sharpened and ready to be administered to the next scientific question.

I remember once bemoaning that because Stan was not at a university, numerous students missed out on all that he had to offer. Wrong, wrong, wrong! STRI offers a wide array of fellowships for researchers at all stages. They all need STRI sponsors. I have counted more than 50 students that Stan sponsored before 1990; surely I have missed many. In addition, since 1986 Stan has acted as sponsor to more that 70 interns and associates who have worked with us on the túngara frog project. He visited my lab in Austin twice a year for a long time; those visits were so heavily booked that I had to sequester Stan at a local pub to have time with him. But that hiding place was found too soon. Finally, there are literally hordes of students who owe Stan deeply. Two now rather famous biologists, one who studies monkeys the other ants, told me long before they were famous that Stan was crucial to the early development of their research forays on BCI. When I informed by mass e-mail numerous colleagues of Stan's death I received a plethora of responses in which the word "love" was used much more than one might associate with "macho" (and "macha") field biologists.

So now we say goodbye, Stan. Thanks for all that you shared, the family, the friends, the tropics, and the frogs. You will not be forgotten. Next rum's on me.

Herpetological Review, 2006, 37(2), 137–138.

John Luther Behler (1943–2006)

PETER BRAZAITIS
Curatorial Affiliate, Department of Vertebrate Zoology
Yale Peabody Museum of Natural History
New Haven, Connecticut 06520-8118, USA
e-mail: croc1@99main.com

and
BILL HOLMSTROM
Department of Herpetology , 2300 Southern Boulevard
Wildlife Conservation Society/Bronx Zoo, New York 10460, USA
e-mail: bholmstrom@wcs.org

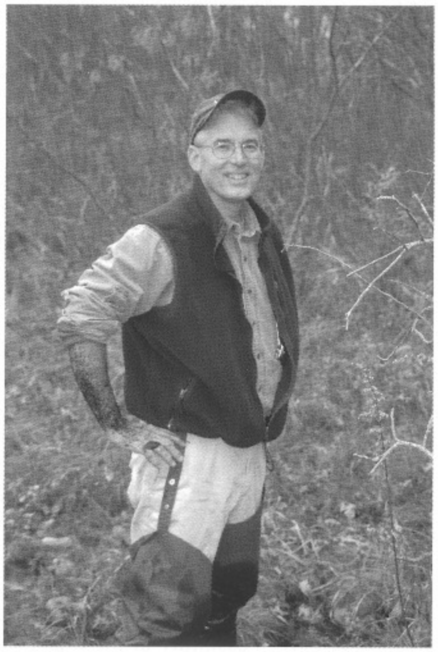
Many scientists achieve fame and immortality as a result of years of dedicated research and productivity in their chosen field. John Behler has achieved both, not only because of his dedication and contributions to conservation and herpetology, but also as a warm human being. He will be long remembered by many whose lives he touched, careers he helped, and for the compassionate counsel he gave when they needed it most.

John was born into a family of dentists. But it was not long before his real passion for the outdoors was evident. He loved to fish, hunt, catch and collect butterflies, and study insects, frogs, snakes, and turtles. He was passionate about natural history. His entry into dental school was abandoned when his father wisely advised him to pursue a career in zoology instead. He majored in zoology at the University of Miami and earned a Master's Degree in Education at East Stroudsburg University in Pennsylvania. During the summer months, John worked for the National Park Service at Indian Town Gap National Park. He taught for a short period at Hobart and William Smith College in upstate New York. His interests, which remained with him throughout his life, soon focused on turtles and salamanders.

John joined the Wildlife Conservation Society in 1970 as a curatorial intern in the Department of Herpetology. He brought his passions with him, and later, as the Curator of Reptiles, he became a conservation icon. He developed the first management plan to save the American crocodile in Florida, and developed programs for the conservation of endangered Madagascan tortoises, to name only a few of his achievements. While Raymond L. Ditmars, the first Bronx Zoo curator of reptiles, was the first to introduce the public to herpetology through popular writings, John brought zoo herpetology into the arena of international conservation. He was particularly concerned with the plight of turtles, crocodilians, and other reptiles around the world, a concern that took him traveling to the far reaches of the globe. He created and administered the first crocodilian Species Survival Program (SSP) for the Chinese Alligator under the American Zoo and Aquarium Association, a program that still stands as a model for the successful conservation and management of an endangered species. He was instrumental in developing captive breeding programs for reptiles at the Society's Wildlife Survival Center on Saint Catherine's Island, off the coast of Georgia. When John ran a program, it was, by definition, going to be successful, despite the shambles he might find it in when he inherited the task.

Yet, he never lost sight of the problems faced by species in his own backyard. John worked tirelessly to save the rare and endangered Bog Turtle, and helped state agencies and local governments in designating and protecting critical wetland habitats. He was instrumental in the creation of the Bog Brook Unique Area, in Putnam County, New York, as a New York State sanctuary for all three indigenous turtle species.

While John might sympathize with the overzealous private collectors who found themselves running afoul of the law for some wildlife infraction, he also worked closely with state, national, and international wildlife law enforcement authorities to provide expertise, training, and advice.



A typical day in the field for John Behler—wet, muddy, and smiling. Photo taken at Delaware Water Gap National Forest, November 2003. Behler and other researchers were conducting a multi-year study of Wood Turtles. Photographer unknown.

His field guides and

books on native and exotic reptiles can be found on bookshelves throughout the US and abroad, and John's popular articles and scientific writings continue to thrill and excite young people and adults alike. His latest work, *Frogs, a Chorus of Color*, co-authored with his wife Debbie Behler, highlights these beautiful and unique creatures and stimulates public concern for amphibian populations, which are declining worldwide. Unfortunately, John died before seeing the publication of what may have been his greatest pride, a book on the reptiles and amphibians of New York State, written in collaboration with the New York State Department of Environmental Conservation.

John always credited his experiences at the Bronx Zoo for teaching him so much about the care and habits of the animals he loved. But John could not imagine the wealth of knowledge and the insights he so casually shared with those around him, including his professional peers.

John is survived by his wife Debbie, his mother Mildred, sister Judy, his children Cindy Sibilia and David Behler, and five grandchildren. Most of all, John is survived by a legacy of willingness to help others in his profession, and a genuine care for the future of all living creatures. We will all miss John and his counsel.

ZOO VIEW

Rarely is a zoo blessed with many prominent curators but New York's Wildlife Conservation Society (WCS), headquartered at the Bronx Zoo, enjoys a worldwide reputation in herpetology because of the writings and diverse backgrounds of five men: Raymond L. Ditmars, James A. Oliver, Herndon G. Dowling, F. Wayne King, and John L. Behler. Our dear friend and colleague, Curator of Herpetology John L. Behler has passed away after a lengthy illness (Fig. 1). The moving tribute to John in this issue written by his co-workers at WCS for so many years—Peter Brazaitis and Bill Holmstrom—clearly shows how an accomplished and effective herpetologist can contribute to conservation outside zoo boundaries (see 2003 Herpetol. Rev. 34:192–193, for example).

John was a prolific writer and was always focused on public education. Here is one recent example—said to be the most successful traveling exhibit at the American Museum of Natural History in New York City was *FROGS! A CHORUS OF COLORS*. This exhibit was created by the staff at Clyde Peeling's Reptiland in Allenwood, Pennsylvania and featured hundreds of living frogs and spectacular graphics. Behler and his wife Deborah A. Behler, editor-in-chief of the Society's *Wildlife Conservation* magazine, produced a splendid companion volume to this exhibit with the same name. Geared primarily to the layman, this lovely book (Sterling Publishing Co., Inc., New York; ISBN: 1-4027-2814-X, 2005), is filled with remarkable pictures, readable text on important aspects of anuran biology, and a strong conservation message.

I have selected some of Behler's important books and papers below to show his versatility across a wide range of herpetological subjects.

Reproduction and Captive Breeding

Charles (Charlie) H. Hoessle

R. Marlin Perkins hired Charles (Charlie) H. Hoessle as a reptile keeper at the St. Louis Zoo in 1963. Only two years later, he was elevated to assistant general curator and by 1969, Charlie was general curator. Charlie continued to rise and in 1972, he became deputy director. In 1982, he was installed as permanent director, a post he held until he retired twenty years later. He has stayed on as director emeritus.

It was fitting that Charlie received the prestigious R. Marlin Perkins award, the highest honor bestowed to a zoo professional by the American Zoo and Aquarium Association. In 2005, Charlie was recognized by zoo supporters in St. Louis with a full-sized bronze statue of him with a Boa Constrictor draped over his shoulders in front of the newly-named Charles H. Hoessle Herpetarium. This historic building—built in 1927—with its beauty and grace, has always been one of my favorites and it is wonderful that he has been recognized for his many accomplishments in our field (Fig. 2). Charlie joins a select list of directors in the United States who specialized in herpetology—Arthur Brown, Roger Conant, Carl Kauffeld, Edward Maruska, James Oliver, R. Marlin Perkins, George Rabb, and John Werler.

The Brazilian Cerrado remains one of the most poorly understood habitats in that country. Among the little known anurans from the Cerrado is a reclusive member of the genus *Leptodactylus* which Peters (1870) described as *Entomoglossus pustulatus*, collected from Ceará, Brazil (Bokermann 1966). Boulenger (1882) reassigned the species to the genus *Leptodactylus*. A number of subsequent publications briefly mention the species by either including it in faunal, distributional, or nomenclatural listings, or by providing short physical descriptions of preserved specimens (Bokermann 1962, 1966; Duellman 1999; Frank and Ramus 1995; Frost 1985; Heyer and Pyburn 1983; Liner 1992; Lutz 1926, 1930; Miranda Ribeiro 1926, 1927; Vanzolini and Heyer 1988), but little else has been reported. The holotype was long believed lost, leading Heyer (1970) to designate a neotype (MCZ 373). Subsequently, the original type has been relocated in Berlin, Germany (ZMB 6951) (Bauer et al. 1995).

Habitat associations.—Little is known of the biology or ecology of this species. These frogs have been primarily associated with Amazon, Cerrado, and Caatinga habitats south of the Amazon River; the four drainage systems for which reliable locality records exist are the Xingu, the Paranaíba, the Araguaia, and the Tocantins in Central Brazil (Heyer 1970). The majority of the locality records associate the species with Cerrado (Heyer 1994). The type specimen was collected in Ceará, Brazil (Peters 1870), an area dominated by Caatinga habitat. Bokermann (1962) reported finding individuals beneath an old boat along the Xingu River. The locality, Posto Jacaré, is located in transitional forest between Cerrado and Amazonian biomes (as are the localities for the new specimens reported herein). Aside from association with riparian habitat, frogs have also been found in patches of marsh-like wetlands within the outlined habitat types, known in Brazil as "vereda." No other habitat information for *L. pustulatus* has been published (Heyer 1994, Heyer, pers. comm.), except for male calling sites (Brandão and Heyer, *in press*).

Habitat description (Locality 1).—In August 2000, we collected two specimens and observed a third along the upper Tocantins River in the state of Tocantins, Brazil. Vereda in the vicinity of the city of Tocantinópolis ranges from mildly disturbed to completely cleared for cattle grazing. We found our specimens in a heavily disturbed clearing with a natural spring that maintains the small wetland area, even in the dry season. During the wet season, the entire cleared area, ca. 50 ha^2, is inundated with water ranging from 0.2–1 m in depth. During the dry season, the wetland is reduced to small patches roughly one tenth the size of the wet season habitat. Tall grass covers the clearing at roughly 0.6 m in height. The ground is uneven and is arranged in a random series of slightly elevated mounds. These mounds become small, soggy "islands" in the wet season and are separated by shallow water. All *L. pustulatus* from this locality were found on these mounds at night. When approached, individuals crawl in a bufonid-like fashion rather than hopping away in a typical leptodactylid fashion. The following anurans were found syntopically: *Leptodactylus ocellatus*, *L. podicipinus*, *Hypsiboas raniceps*, *Dendropsophus minutus*, *Scinax* sp., and *Pseudis tocantins*.

Habitat description (Locality 2).—The city of Peixe, Tocantins State, is connected to the "Peixe Angical" hydroelectric impoundment of the Tocantins River by a road that crosses the Tocantins River before reaching the dam. That road is fringed by area cleared for the grazing of cattle. Patches of vereda are common along the road. On the right bank of the Tocantins River, immediately after the road crosses it, is a patch of vereda. We examined the habitat on 25 April 2005 at 2000 h and 17 June 2005 at 1900 h. The wetland is ca. 6 ha^2 with water depths ranging from .01 to 2.1 m depth. The vereda is maintained throughout the year by springs and aquatic vegetation is present. The edges of the wetland, and small islands within, are covered by grass 0.4 m in height. All *L. pustulatus* at this locality were found on muddy banks of the wetland, among clumps of grass. The following anurans were found syntopically: *Pseudis tocantins*, *Dendropsophus anataliasiasi*, *D. minutus*, *D. cruzi*, *D. nanus*, *Hypsiboas raniceps*, *Leptodactylus ocellatus*, *L. fuscus*, *L. labrynthicus*, *L. podicipinus*, *L. troglodytes*, *Physalaemus cuvieri*, and *P. nattereri*. We observed Cuvier's Dwarf Caiman (*Paleosuchus palpebrosus*), a potential predator, in the wetland.

Color in life.—The dorsal coloration of individuals range from a dark, forest green, to dark brown, with darker brown or black irregularly shaped and spaced spots. In contrast to other *L. pustulatus* without dorsolateral ridges (Heyer and Pyburn 1983), these specimens have six small, elevated dorsolateral ridges extending along the dorsum to the vent with an uneven surface. A maroon V-shaped pattern extends from behind each eye to the nasal openings. A faint black line also extends from the base of each eye to the nasal openings. The pupils are horizontal and black. The iris is a faded copper color marked by irregularly spaced black reticulations that extend to the edge of the eye. The ventral pattern and coloration of *L. pustulatus* is a distinguishing character from other anurans, save for *L. podicipinus*. The ventral ground color ranges from charcoal gray to black and can change within 20 minutes from gray to jet black or vice versa. Circular and ovoid spots cover the ventral surface extending from the throat covering to the groin and undersides of the legs and arms, as well as onto the flanks. The spots wrap around the throat and onto the lower lip. Syntopic *L. ocellatus* and "*L. podicipinus*" also have white spots of similar proportion on their lower lip which confuses visual iden-

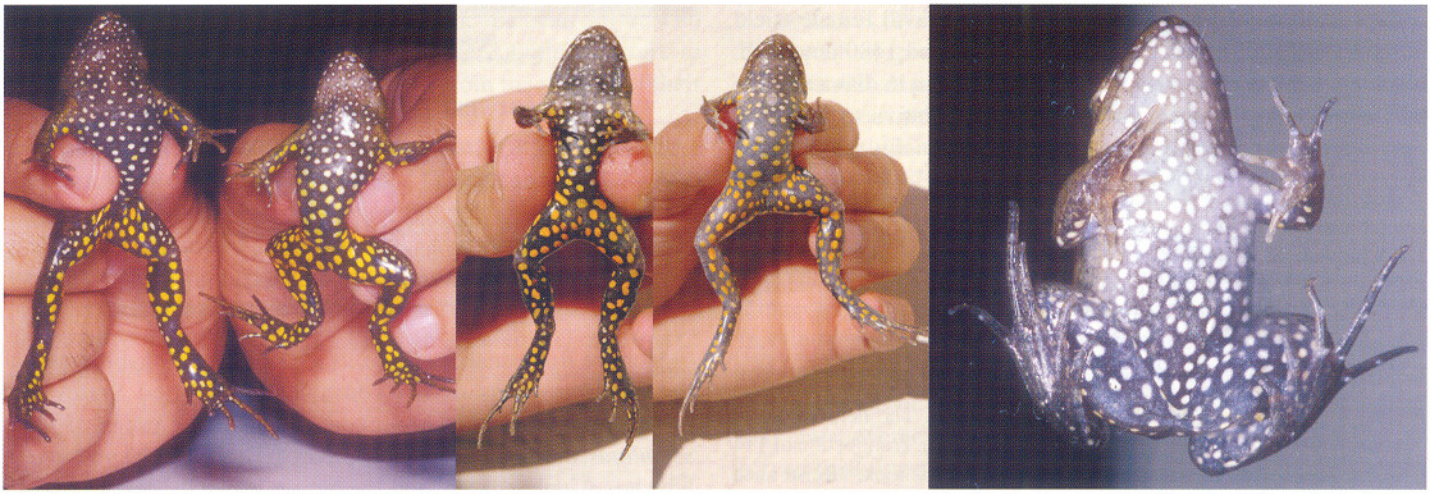

FIG. 1. The ventral surface of *Leptodactylus pustulatus* demonstrating ventral color in life and variation in color and pattern. From left to right: HLR20 and HLR21 from outside "Paudo Chapinha:" wetland on the left bank of the Tocantins River: Tocantins State: Brazil; NAT1222, NAT1223, and NAT1228 from the road connecting the town of Peixe, and "Peixe Angical" hydroelectric impoundment: wetland on the right bank of the Tocantins River: Tocantins State: Brazil. Note, NAT1228 is a juvenile with only faint traces of the orange coloration filling spots on the outer thighs and arms.

tification when facing an individual from a distance. The ventral spots on *L. pustulatus* do not connect and are white in the throat and chin region. All of the spots near the groin and lower abdomen range from a brilliant orange to canary yellow in adults. Individual variation exists in the relative number of colored versus white spots, and in the progression of the orange spots up the ventral surface toward the animal's head (Fig. 1). In most individuals, orange colored spots can be found on the underside of the upper arms, even if the orange spots don't extend far up the ventral surface. In a resting position, the spots are visible on the chest and lower lip when approaching the animal from the front. Two juvenile frogs were collected at the Peixe locality. The spots on their ventral surface were primarily white. The orange coloration of the spots on the thighs and groin area was faint (see Fig. 1). This observation suggests that either 1) juveniles do not have well defined orange colored spots early in life, or 2) that some individuals never develop well defined orange or yellow spots. Because all adults observed from this locality and elsewhere have had well defined orange or yellow colored ventral spots, the first hypothesis is the likely condition. Accordingly, this increases the likelihood of confused identifications between juvenile *L. pustulatus* and *L. podicipinus* (similarly sized and colored dorsally—also with white spots on the ventral surface). One discriminating character is that in *L. pustulatus*, the ventral surface of the tarsal units have distinct white spots, whereas in *L. podicipinus* the surfaces are mottled rather than clearly spotted (W. R. Heyer, pers. comm.).

TABLE 1. Morphometric measurements for specimens of *Leptodactylus pustulatus* from (1) outside "Paudo Chapinha": wetland on the left bank of the Tocantins River: Tocantins State: Brazil, and from (2) the road connecting the town of Peixe, and "Peixe Angical" hydroelectric impoundment: wetland on the right bank of the Tocantins River: Tocantins State: Brazil. All measurements taken using digital calipers, in mm: SVL = snout to vent length, HW = head width, HL = head length, IOD = inter-ocular distance, END = eye to nostril distance, TD = tympanum diameter, FeL = femur length, TL = tibia length, FL = foot length, Juv. = juvenile. All specimens deposited in the collection at the Universidade Católica de Goiás, Goiás, Brazil.

Reproductive output.—We collected one gravid female (field number NAT1223) at the Peixe locality. She had 1480 unyolked, black eggs in her abdomen. All eggs were 1 mm in diameter. She had a noticeably greater girth to her body relative to two non-gravid females collected at the Tocantopolis locality.

Acknowledgments.—We thank W. R. Heyer for his comments and considerable assistance throughout this project. We would also like to thank J. P. Caldwell, S. R. Richter, and W. W. Lamar for their comments on the manuscript. Financial and logistical support in Brazil was provided by SYSTEMA NATURAE – Consultoria Ambiental Ltda.

Rain-Harvesting in a Wild Population of *Crotalus s. scutulatus* (Serpentes: Viperidae)

MICHAEL D. CARDWELL
3150 Prince Henry Drive
Sacramento, California 95833, USA
e-mail: mikecardwell@comcast.net

Mohave Rattlesnakes (*Crotalus s. scutulatus*) inhabit many of the desert regions of the southwestern United States and northcentral Mexico. Throughout much of the range of *C. s. scutulatus*, the dominant plant is Creosote Bush (*Larrea tridentata*), which is widely spaced, and the terrain is mostly devoid of rock outcroppings and other significant topographic features. This habitat is also characterized by dry, porous soils that rapidly absorb rainfall, creating little opportunity for surface water to accumulate. Most precipitation in the Mohave Desert, where this study was conducted, occurs during the winter. Summer monsoon rains are less predictable and less significant than in the more southern Sonoran and Chihuahuan Deserts (Jaeger 1957), where *C. s. scutulatus* also occurs.

Several authors have described viperid snakes drinking water from the external surfaces of their own skin. Bogert (1927) describes a technique for captive husbandry of "rattlesnakes taken on the desert miles from water" as requiring water to be "sprayed upon them, as well as upon the rocks in their cage." He goes on to describe the snakes "sucking the water off the rocks and sometimes off their own backs." Also referring to captive animals, Hediger (1964) describes "some rattlesnakes" as preferring to "drink drops from the scales on their own bodies." Greene (1997) describes watching a wild Terciopelo (*Bothrops asper*) "drinking rain droplets off her own skin" in a Costa Rican rainforest. Andrade and Abe (2000) report captive juvenile Brazilian Lanceheads (*Bothrops moojeni*) coiling when sprayed with water, which was trapped between body loops and ingested. Captive Peringuey's Adders (*Bitis peringueyi*) from the Namib Desert have twice been reported to flatten their bodies when sprayed with water, which they then "drink" (Robinson and Hughes 1978) or "lick" (Louw 1972) from their own skin. Aird and Aird (1990) reported a captive adult female Great Basin Rattlesnake (*Crotalus oreganus lutosus*) in an outdoor enclosure flattening her body, forming concentric coils, and drinking rainwater trapped between the coils. A single observation of a wild xeric rattlesnake, *Crotalus oreganus concolor*, drinking rainwater from its skin was reported by Ashton and Johnson (1998).

Body posturing has been reported to enhance the collection of water from the skin by some desert lizards, including *Phrynocephalus helioscopus* (Schwenk and Greene 1987), *Phrynosoma cornutum* (Sherbrooke 1990), *P. platyrhinos* (Peterson 1998), *P. modestum* (Sherbrooke 2002), and *Trapelus pallidus, T. mutabilis,* and *T. flavimaculatus* (Vesely and Modry 2002). The term "rain-harvesting" was first used by Sherbrooke (1990) to describe the combination of integumental microstructure that enhances capillary movement of water and associated stereotypical posturing by *Phrynosoma cornutum* to collect and ingest rainwater.

I herein use "rain-harvesting" to describe the behavior of wild *C. s. scutulatus* by which they adopt a stereotypical posture to collect rainwater, which they then drink from the surface of their skin.

Methods.—Ten male and 10 female adult (> 180 g) Mohave Rattlesnakes were surgically implanted (Reinert and Cundall 1982) with temperature-sensing radio transmitters (model SI-2T, Holohil Ltd., Ontario, Canada) and radio-tracked for periods ranging from 18 days to 32 months (mean = 16 months).

Observations were made from August 2001 through April 2004, which involved > 2700 individual encounters with telemetered *C. s. scutulatus* and 84 chance encounters with 40 non-telemetered specimens. These observations were made in all seasons, at all times of day, and in a wide variety of weather conditions, including rainfall.

The study site is in the western Mohave Desert near Victorville, San Bernardino County, California, USA (ca. 34°36'N, 117°10'W) on a Creosote Bush-dominated bajada at a median elevation of about 975 m.

Current and historical precipitation data were obtained from the National Oceanic and Atmospheric Administration for its "Victorville Pump Plant" station (COOP ID 049325), located 14 km SW of the study area.

Results.—Individual *C. s. scutulatus* were visible on 1633 occasions. In 1097 of these observations (67%), they were found motionless in round "resting/ambush" coils, in which the anterior body was coiled on top of and covering the posterior body and tail. The head rested on top, oriented to face away from the center of the coil, with the axis of the head usually on a radius of the coils. The crown of the head was usually level or the nose was slightly elevated (Fig. 1).

In 12 of 16 observations during rainfall, the snakes were observed to be coiled with the body spiraling out from the tail in the center; the coils of the anterior body were adjacent to, rather than on top of, the coils of the posterior body. The abdominal area was extraordinarily flattened dorso-ventrally, maximizing the surface area exposed to the rain. Adjacent posterior abdominal coils were in contact, forming a shallow trough between them where rainwater collected. The position of the head was adjusted to a nose-down attitude, placing the rostral area in the trough formed by the adjacent abdominal coils (Fig. 2). This posture and behavior was also observed on six additional occasions shortly after rainfall had stopped but while the snakes were still wet. These 18 observations involved 12 different animals during 9 storms in 3 calendar years.

In each case where rain-harvesting behavior was observed, the snake positioned its head so that the rostral area was within about 2 mm of, or actually in contact with, the animal's skin. Slight rhythmic movement could be observed in the temporal-mandibular musculature and the rostral area was moved every few seconds to different areas of the trough between adjacent coils. Although actual jaw movement could not always be seen, water could be observed to disappear as it came into contact with the snake's rostral area.

On 10 July 2002, an 828 mm SVL (snout–vent length) male *C. s. scutulatus* (Css25) was observed just as a summer evening thunderstorm struck. The snake was in a resting/ambush coil, under the edge of overhanging Mormon Tea (*Ephedra nevadensis*) foliage, when a few large scattered raindrops began to fall. In < 10 seconds, he moved about 20 cm to a position that was not overhung by the shrub, assumed the rain-harvesting posture and began to search for water on his own skin in a very animated manner. This occurred even before he or the surrounding substrate was visibly wet. Immediately after this observation, I returned to a 770 mm SVL female (Css20) that had been visited 22 minutes before and found her in rain-harvesting posture, having also moved from under foliage (*Larrea*), where she had earlier been in a resting/ambush coil.

On three other occasions, Mohave Rattlesnakes were observed to move away from their rain-harvesting positions (usually to retreat from the observer) and the substrate under each snake was noted to be dry, contrasting with the adjacent soil that had been darkened by moisture.

Study animals ignored large granite rock outcrops in parts of the study site where temporary puddles of rainwater can be expected to occur. In some areas frequented by the study animals,

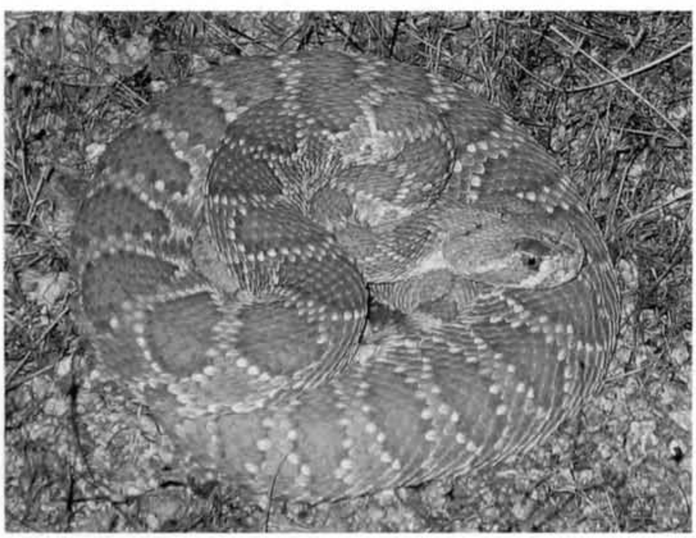

Fig. 1. *Crotalus s. scutulatus* (Css42, 1 May 2004) in stereotypical resting/ambush posture.

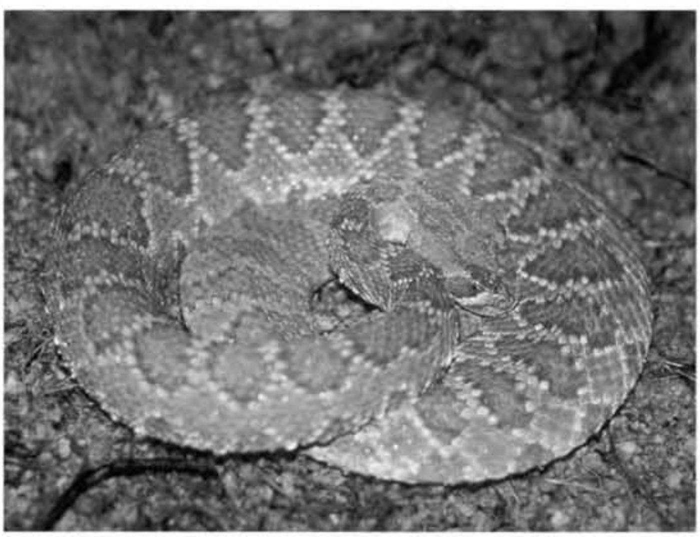

Fig. 2. *Crotalus s. scutulatus* (Css03, 30 October 2001) in stereotypical rain-harvesting posture.

the ground is littered with cobble (stones 65–256 mm) that accumulated rainwater on their surfaces in quantities that appeared at least comparable to the water that collected on the snakes' bodies. While other small creatures (e.g., *Hadrurus* scorpions) drank from these small rocks and from dripping vegetation, *C. s. scutulatus* were never observed to use water from these or any surfaces except their own bodies.

Crotalus s. scutulatus were observed harvesting rainwater in March, April, July, August, September, October, and November. Mean body and air temperatures during observed rain-harvesting were 18.2°C (range 12 – 32; N = 13) and 17.6°C (range 11 – 30; N = 16), respectively. Fewer body temperatures were recorded than air temperatures because of transmitter failure (N = 1) and chance observations of non-telemetered snakes (N = 2).

Study animals were visited on 22 occasions during rainfall events in November, January and March. With the exception of one mid-March observation, there was no indication that the animals emerged from their winter shelters (mammal burrows) to drink.

Discussion.—*C. s. scutulatus* are ambush predators and, in this study, 67% of their time above ground was spent in resting/ambush coils. By minimizing exposed skin, this position minimizes transdermal moisture loss in conditions of very low humidity (Cohen 1975). Compared to the resting/ambush coil, the rain-harvesting posture increases exposed skin surface (thereby intercepting more rain), decreases the slope of the lateral skin surface (thereby slowing water runoff), and creates troughs between adjacent coils where water accumulates. Although water is also available on the surface of small stones and foliage during and immediately after rain, the rain-harvesting posture is more efficient in that it does not require time to be spent during typically brief storms searching for a suitable surface from which to drink.

Drinking snakes' core body temperatures were very close to the surrounding air temperatures (mean difference < 1°C) and revealed that they were willing to endure body temperatures as low as 12°C to harvest rainwater. Sherbrooke (1990) observed nocturnal emergence, presumable at lower temperatures, of Texas horned lizards (*Phrynosoma cornutum*) to harvest rain during nighttime storms.

Desert rattlesnakes, like other desert animals, depend on metabolic water obtained from the food they consume. Nonetheless, it has been shown that reptiles cannot produce enough metabolic water to entirely compensate for water loss (Nagy 1987). *Crotalus s. scutulatus* appears to be adapted to efficiently exploit one of the rarest yet most important resources in xeric environments, especially considering that nearly 70% of annual precipitation in this study area occurs from December through March (National Climatic Data Center 2002), when cold temperatures apparently prevent *C. s. scutulatus* from taking advantage of it.

Two observations of *C. s. scutulatus* moving out from under foliage at the first hint of rain suggest that these snakes take up rainfall-harvesting positions very early in a rainfall event. It should be noted, however, that these two observations were made during a storm season (October 2001–September 2002) that yielded 71% less precipitation than the 30-year mean for the area (National Climatic Data Center 2001–2002 and 2002). Observations of dry ground under other rain-harvesting specimens is consistent with such early movements but is equally consistent with those snakes being in suitable rain-harvesting locations before rainfall began.

Acknowledgments.—I thank William Hayes, Sean Bush, and Loma Linda University for a wide variety of essential advice and support. Arizona State University West provided additional equipment. David Hardy Sr., Gordon Schuett, Dale DeNardo, Tracy Brown, Roger Repp, Emily Taylor, and Matt Goode contributed important suggestions regarding surgery, field techniques, and data processing. Allen Hawley and Cliff Jessen contributed essential veterinary supplies. Eric Dugan, Chris Rodriguez, Denise Garland, and Shannon Garland provided assistance in the field. Wade Sherbrooke and two anonymous reviewers provided valuable comments on the manuscript. Cemex Corporation consented to the study being partially conducted on its property. The Loma Linda University Animal Research Committee approved the study, which was carried out under California Department of Fish and Game scientific collecting permits nos. 801125-01, 801165-01, and 801102-04.

Human transportation infrastructures, such as roads, can adversely affect animal populations via fragmentation (Forman and Alexander 1998; Mader 1984) and habitat deterioration due to construction (Ritters and Wickham 2003), changes in predator/prey concentrations (Dijak and Thompson 2000) and vegetation composition (Angold 1997), and the spread of invasive species (Tyser and Worley 1992) (for summary references see Forman et al. 2003). Direct mortality has been demonstrated for many animals, including mammals (Groot Bruinderink and Hazebroek 1996; Havlín 1987), and amphibians and reptiles (e.g., Ashley and Robinson 1996; Hels and Buchwald 2001; Smith and Dodd 2003). Other land transportation networks, such as railroads, can result in direct mortality due to collisions with trains, although this has been primarily documented for mammals (see Van Der Grift 1999 for review). Although some lizards may benefit from railroad structures (Blanke 1999), the railroad bed itself may be lethal for smaller animals that can become trapped between the rails, where they may be susceptible to predation or physiological stress. Railroads can also form barriers, either physically (inability to cross) or behaviorally (avoidance), that can result in fragmented populations (Groot Bruinderink and Hazebroek 1996). For example, Van Der Grift (1999) points out that few Hedgehogs (*Erinaceus europaeus*) are killed by trains, but the structure of the railroad may act as a barrier to movement.

Eastern Box Turtles (*Terrapene carolina*) are found throughout most forests of the eastern United States. In many regions, their habitat is traversed by railroads. Points where roads intersect railroads (i.e., railroad crossings) likely increase the probability of turtles entering and becoming trapped between railroad rails. Apparent railroad-induced mortality has been documented for *T. carolina* due to individuals becoming trapped between the rails (Dodd 2001; Palmer and Braswell 1995). Anecdotal evidence of 10–15 *T. carolina* shells of varying sizes in a 5-km section of railroad in north Florida, suggests that turtles have difficulty crossing or escaping from between the rails (Pierson Hill, pers. comm.).

In this study, we examine the potential impacts of railroads on *T. carolina* by testing their ability to escape from between railroad tracks. Additionally, we estimate the temperatures that *T. carolina* experience while trapped. Finally, we use Geographic Information System (GIS) data to determine the likelihood of a turtle encountering potential entry and exit points along railroads within our study area.

METHODS

We conducted our study near the town of Davidson in northern Mecklenburg and southern Iredell counties, North Carolina, USA, on a seldom-used stretch of railroad track typical of those in the region. The railroad rails are T-shaped and approximately 190 mm high and 70 mm wide at the top of the rail (Fig. 1).

We tested 12 adult *T. carolina* (8 male, 4 female) with a mean ± SE body mass of 383.1 ± 14.4 g). Mean ± SE measurements of the turtles we tested were: carapace length = 130.1 ± 1.7 mm, plastron length = 126.1 ± 1.4 mm, shell width = 103.4 ± 1.3 mm, and shell height = 62.3 ± 1.3 mm (Fig. 1). All turtles were captured by members of the Davidson College Herpetology Laboratory or the Davidson community and tested between 4 September and 2 October 2004. Turtles were maintained in the laboratory for < 2 weeks prior to experiments and were provided with food and water *ad libitum*. No animals used in the experiments were injured or displayed signs of deteriorating health while in captivity. After completion of the experimental trials, we released turtles at their original capture locations.

Experiment 1. Can box turtles climb over railroad rails?

To examine the ability of *T. carolina* to escape from railroad tracks, we placed turtles between the rails of a railroad at a predefined common location (i.e., starting point) and oriented them in one of three randomly chosen directions: facing away from the observer or towards the observer's left or right. After releasing the turtle, the observer sat motionless on the track at least 20 m away and remained 20–40 m away from the turtle for the duration of each experiment. The turtle's movements and behavior were followed using a spotting scope (Spacemaster, 15–45x zoom; Bushnell Corporation, Overland Park, Kansas). Trials started when the turtles emerged from their closed shells and began moving. Trials ended after 60 min or when the turtles escaped from the track. We recorded the frequency of the following behaviors during the trials: 1) Exploring – when a turtle stopped and extended its neck, apparently attempting to assess the surrounding environment and/or look over the tracks; 2) Climbing attempt – when a turtle was oriented perpendicular to and tried to climb over a rail; 3) Falling – when a turtle fell on its back after an attempt to climb; 4) Retraction – when a turtle's limbs and head were drawn inside the shell; 5) Direction change – when a turtle substantially altered its course from a straight-line movement.

Using a measuring tape, we recorded to the nearest 0.1 m, 1) the distance between the starting point and the furthest point that a turtle reached (referred to as "furthest distance"); and 2) the modal sum of the displacement vectors' lengths ("total distance"). Turtle walking speed was estimated at specified distances using predefined markers not visible to the animals.

We conducted the experiment on a 1 km section of railroad with adjacent forested land on either side of the tracks. Secondary growth mixed pine and hardwood forest on both sides of the railroad may have provided visual cues to the turtles that preferable habitat was available nearby. The forest also helped to reduce noise from nearby streets and provided shade, easing possible thermal stress to the turtles during our tests.

Experiment 2. Will box turtles escape at railroad crossings?

To test turtle behavior upon reaching a railroad crossing (i.e., intersection of a road with a railroad), we positioned all 12 subjects between railroad tracks, facing a railroad crossing 5 m away.

This site (ca. 3 km N of the location of Experiment 1) was a section of the railroad that ran between a large grass field and a two-lane road with a moderate amount of traffic running parallel to the track. A second road with low traffic levels crossed the railroad and intersected with the two-lane road. The area between the tracks at the crossing was filled to the level of the road and rail with asphalt; large wooden beams separated the track from the asphalt. The asphalt sloped at ca. 45° up to the level of the road, which allowed turtles to climb up from the railroad bed.

Observations began once the turtle started moving and lasted until one of the following events occurred: 1) the turtle turned around, walked away from the railroad crossing and passed the starting point; 2) the turtle climbed up on the asphalt, crossed the road, and continued traveling between the rails on the other side of the road; 3) the turtle moved from between the tracks towards the grass field, or 4) the turtle moved from between the tracks and traveled towards the two-lane road. The frequency of behaviors such as climbing attempts and falling (defined above) were also recorded. The observer stayed < 5 m from the turtle throughout the experiment to ensure that the turtle did not get hit by vehicles, but attempted to disturb the turtles as little as possible.

To determine the likelihood that a turtle would encounter potential entry and exit points along the railroads within our study area, we calculated the mean distance between railroad crossings using mile-marker data in a GIS for railroads passing through the towns of Davidson, Cornelius, and Huntersville, North Carolina (Mecklenburg County GIS files, Mecklenburg County Information Services and Technology).

Experiment 3. How long does it take a turtle to overheat between tracks?

We experimentally measured the changes in turtle body temperature (T_b) when placed on a railroad tie equidistant from both railroad tracks. We conducted this experiment in an area of full-sun exposure from late morning (ca. 1000 h) to early evening (ca. 1900 h) on three mild days (T_{air} ca. 22°C) during late September 2004. We used two turtles in this experiment and two different turtles during preliminary trials. All were collected after being recently killed on the road but had minimal damage to the shell and body. They had similar dimensions to the living turtles used in our study, and were kept frozen until use. To estimate shell temperature, we glued a microdatalogger (Thermochron iButton, Dallas Semiconductor, Inc., Dallas, Texas, USA) to the top of each dead turtle's carapace (Grayson and Dorcas 2004). Because cloacal temperatures of *T. carolina* correlate well with core turtle temperatures (Russo 1972), we recorded core body temperature by inserting a thermistor attached to a datalogger approximately 7 cm into the cloaca (StowAway XTI Temperature Logger, Onset Computer Corp., Bourne, Massachusetts, USA). Both dataloggers were set to record every 5 min and had a resolution of ± 0.5°C (Grayson and Dorcas 2004; Onset Computer Corp.). We obtained data on air temperature from an automated weather station located ca. 2 km from the test site.

Results

Experiment 1. Can box turtles climb over railroad rails?—Only one of the 12 turtles tested successfully climbed over the rail and escaped from between the railroad tracks. All but three turtles made at least one attempt to climb the rails during the 1-h experiment. Of 42 climbing attempts, 11 were made at connecting brackets that joined two consecutive rails. The turtle that successfully climbed over the rail had the highest number of overall escape attempts (12) and was able to climb over the tracks at the connecting brackets. Some turtles that failed in their attempts to climb the rails tried to escape more frequently than others (mean = 3.75 ± 0.94 attempts; range = 1–8 attempts; N = 8). While attempting to climb, two turtles fell on their backs, but managed to right themselves within a few seconds.

Overall, turtles traveled primarily in straight lines. The mean furthest distance the turtles traveled while between the rails was 79.4 ± 13.2 m (range = 37.3–188.3 m). Two turtles moved more than 100 m; most moved between 45 and 70 m. Mean total distance traveled while between the rails was 89.9 ± 13.05 m (range = 37.3–188.3m) because some turtles changed directions several times. Directional changes occurred frequently, but were generally restricted to short time periods within the test (mean = 22.6 ± 4.7 direction changes per turtle; range = 3–49). Turtles walked on railroad gravel and ties at speeds ranging from 0.083 to 0.056 m/s (5 m in ca. 60–90 s) during at least part of each trial when they were not stopping or exploring the surroundings. During the testing period, turtles showed signs of exploring on average 46 ± 7.52 times per hour (range = 15–87). Three turtles retracted into their shells during the trial; one of these retractions occurred as a person walked on the tracks next to the turtle. Three other turtles buried themselves under piles of leaf litter that had accumulated on the inside of one of the rails.

Experiment 2. Will box turtles escape at railroad crossings?—Of the 12 turtles tested at the railroad crossing, five escaped and crawled towards the grass field, four escaped and moved towards the nearby moderately-trafficked road, two continued straight and remained between the tracks on the other side of the railroad crossing, and one turned back before it reached the railroad crossing.

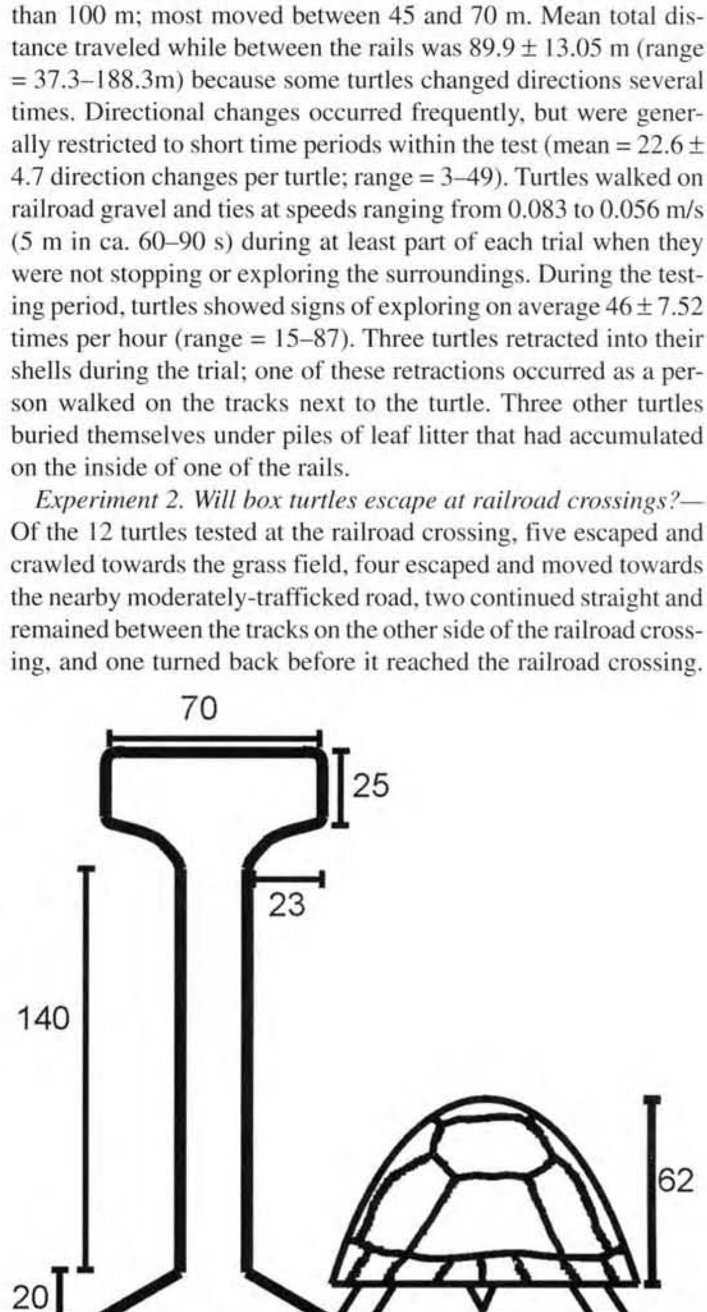

Fig. 1. Mean size of tested Eastern Box Turtle (*Terrapene carolina*; N = 12) compared to railroad track rail dimensions (in mm).

During the course of this experiment, four turtles made eight climbing attempts. The turtle successful at escaping during Experiment 1 accounted for five of the climbing attempts, although it fell over on its back and had to right itself three times.

The mean distance between consecutive railroad crossings in the study area was 379.6 m (range: 48.3–1223.1 m); 30% of the crossings were less than 200 m apart, 16% of the crossings were between 200 and 300 m apart, and 54% were more than 300 m apart.

Experiment 3. How long does it take a turtle to overheat between tracks?—The T_b and shell temperatures of the two dead *T. carolina* tested in late September reached temperatures considerably higher than the air temperature by about noon and remained high most of the day (10–20°C > T_{air}; Fig. 2). The two turtles' T_b and shell temperatures were nearly identical throughout the day. The turtles' core temperatures (maximum = 40.5°C; temperature increase = 0.31°C/h) did not reach mean lethal T_b for the subspecies *T. carolina triunguis* (42.98 ± 1°C; Sturbaum 1981). However, it approached critical thermal maximum (41°C for *T. ornata luteola*; Plummer et al. 2003), defined as the point at which a turtle becomes incapable of coordinated locomotion. Estimated shell temperature stayed consistently higher than core T_b throughout the day and peaked at 48.5°C (Fig. 2).

Discussion

Our results indicate that adult *T. carolina* often cannot escape when trapped between railroad tracks. Most turtles clearly have the ability to escape at railroad crossings, although they may encounter unfavorable conditions (e.g., automobile traffic) upon escaping. While between railroad tracks, turtles can quickly reach critically high body temperatures, even on relatively mild days.

The failure of turtles to climb over the railroad tracks might result both from physical and behavioral characteristics of *T. carolina*. A comparison of turtle and rail dimensions clearly illustrates that the rails represent a considerable height obstacle (Fig. 1). Although a full-grown *T. carolina* erect on its hind legs can sometimes reach the top of the rail, they generally cannot pull themselves over to escape. Willbern (1982) reported several instances of *T. carolina* climbing a 77 cm vertical wire mesh fence. In contrast, the shape and smoothness of a railroad rail, and potentially the high temperature of the rail, appear to impede successful climbing by adult turtles (Fig. 1). Although hatchling and juvenile *T. carolina* might be able to crawl under rails, especially where the gravel underneath the track has been removed, their small size makes them more prone to rapid, and potentially lethal, increases in T_b.

When faced with obstacles, *T. carolina* will often travel along the edge of habitat boundaries such as roads, forest edges, and streambeds, rather than attempting to climb (Lemkau 1970). Our data support this observation because the turtles we tested tended to spend most of their time walking rather than trying to climb over railroad rails. However, because we conducted our experiment under conditions without thermal stress (i.e., in the shade), turtles may not have been as motivated to try to escape quickly from between the railroad rails. When turtles did escape from railroads at crossings, many moved towards a nearby road rather than moving towards a grassy field, thus increasing their probability of being struck by vehicular traffic (Carr and Fahrig 2001; Hels and Buchwald 2001).

We suspect that most turtles that suffer mortality on railroad tracks enter via a railroad crossing (an intersection of a road and a railway where the pavement levels off with the rails). Even in the suburban areas of our study site, the distance between approximately 50% of the railroad crossings was greater than 300 m. The time required for turtles to travel this distance would be at least 1.5 h, assuming the turtle walked continuously at the speeds we measured (comparable to Adams et al. 1989; Lemkau 1970; Muegel and Claussen 1993; Strang 1983).

When trapped between railroad rails, *T. carolina* may quickly reach critical T_b. *Terrapene* spp. thermoregulate behaviorally primarily by varying activity periods and choosing particular microclimatic conditions (Converse 1999; Ernst and Barbour 1972; Reagan 1974). However, railroad tracks rarely provide habitats conducive to behavioral thermoregulation and once air temperature reaches 50°C, *T. carolina* are unable to maintain T_b's within their tolerance limits (Sturbaum 1981). A similar situation was documented in Madagascar, where Radiated Tortoises (*Geochelone radiata*) fell in a steep embankment on the side of an unfinished road and died of sun exposure or drowning (Goodman et al. 1994).

Most research on thermoregulation in *Terrapene* spp. has been conducted with *T. ornata*. do Amaral et al. (2002) failed to conclude whether *T. ornata* has a higher thermal tolerance, more precise physiological methods of thermoregulating, and a potentially higher critical thermal maximum and lethal T_b than the forest-inhabiting *T. carolina*. However, *T. ornata* selected for higher tem-

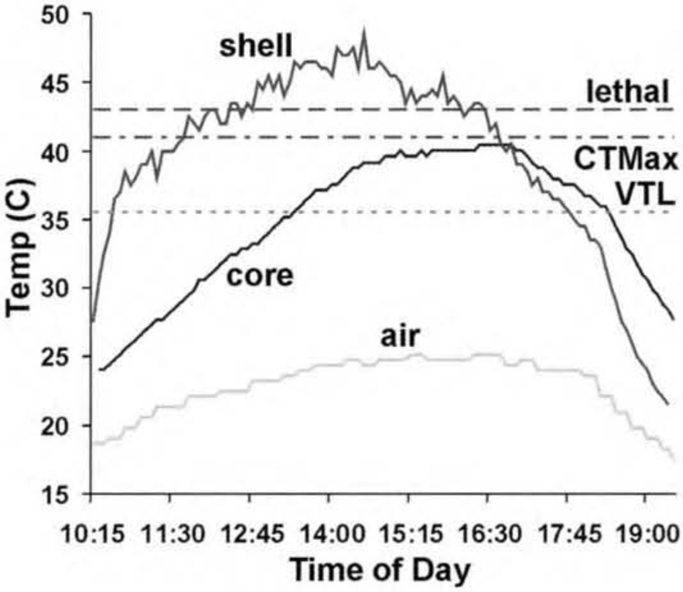

FIG. 2. Core and shell temperatures of a freshly dead Eastern Box Turtles (*T. carolina*) between railroad tracks on 25 September 2004, southern Iredell County, North Carolina. Shell and core temperatures peaked respectively at 48.5°C and 40.5°C; both were consistently higher than the air temperature by 10–20°C. Measured T_b approached estimated lethal T_b for *T. carolina triunguis* (42.98 ± 1°C; Sturbaum 1981). The critical thermal maximum (CTMax) of 41°C and maximum voluntary tolerated level (VTL) of 35.5°C (Plummer et al. 2003) for *T. ornata luteola* may be higher than those of *T. carolina* (Sturbaum 1981) because they tend to choose higher T_b (do Amaral et al. 2002).

peratures than *T. carolina*. Therefore, even though core temperatures in Experiment 3 (Fig. 2) did not quite reach critical levels for *T. ornata*, the highest temperatures recorded might represent critical T_b for *T. carolina*. Two preliminary shorter trials on slightly warmer days (T_{air} approximately 28.5°C at 1500 h) resulted in faster temperature increase (0.61°C/h and 0.42°C/h, similar to Bethea 1972) than the rate of 0.31°C/h for our trial on a relatively mild day (Fig. 2). On these warmer days, it would have taken approximately 4.5 h for a turtle with an initial T_b of 20°C to reach lethal T_b. During all of our temperature tests, the dead turtles' T_b surpassed the maximum preferred voluntary locomotory temperature of 32°C (Adams et al. 1989).

We stipulate that the presence of railroad tracks is detrimental to the health of *T. carolina* populations. Even in the suburban areas of Davidson, approximately one-half of the railroad crossings are separated by what are likely lethal distances for *T. carolina*. Even though a higher number of crossings may increase the chance for escape, individuals whose home ranges border the infrastructure would also be more prone to get trapped between the tracks. Furthermore, railroads in forested regions with fewer railroad crossings may act as physical barriers for exchange of genetic material and decrease the long-term survivability of *T. carolina* populations.

Several investigators have suggested structures such as road tunnels to reduce road mortality (Langton 1989; Messmer and West 2000); structures that reduce the possibility of turtles becoming trapped within railroad rails should be investigated. Additionally, formal studies are needed to evaluate the long-term effects of railroads on *T. carolina* populations.

Most species of the genus *Eleutherodactylus* Duméril & Bibron, 1841 are direct developers with eggs laid in terrestrial sites (Wake 1978). Internal fertilization occurs in two species and may be more widespread within the genus (Townsend et al. 1981; Townsend and Stewart 1994). Live-bearing occurs in at least one species (*Eleutherodactylus jasperi*; Wake 1978). Despite these uncommon reproductive features among anurans, detailed aspects of reproductive biology are known for only a few species of the genus (e.g., Diesel et al. 1995; Donnelly 1999; Lutz 1944; Lynn and Lutz 1946a, b; Ovaska and Rand 2001).

Eleutherodactylus binotatus is a common species distributed along Atlantic Rainforest in Brazil but data on its natural history are scarce (Haddad and Sazima 1992; Pombal and Gordo 2004). The objects of this study are: A) to present data on *E. binotatus* female reproductive investment verifying the correlation between female snout–vent length and the number of ovarian follicles of the largest size class; and B) to analyze the reproductive seasonality in *E. binotatus* by evaluating the seasonal variation of total ovarian mass, the number, and mean diameter of ovarian follicles of the largest size class.

We examined 36 adult female *Eleutherodactylus binotatus* collected in a fragment of Atlantic Rainforest (22°01'S 43°31'W; ca. 600 m above sea level), at Municipality of Belmiro Braga, State of Minas Gerais, Southeastern Brazil. Individuals were collected during three seasons: the first wet season from September 2000 to March 2001; the dry season from April to September 2001; and the second wet season from October 2001 to March 2002. Specimens are housed in the herpetological collection of Museu Nacional, Rio de Janeiro, Brazil (MNRJ 27371–72, 27376, 27380, 27383, 27386–87, 27394, 27397, 27404, 27409, 27411, 27414, 27417–18, 27420, 27422–24, 27446, 27448, 27451–52, 27460, 27474–78, 27490, 27492-93, 27556, 28317–18, and 28479).

Reproductive maturity of adult females was determined by oviduct condition according to Lynch and Duellman (1997). The snout-vent length (SVL) was measured with calipers to the nearest 0.1 mm. Ovaries were removed and weighed on an electronic balance to the nearest 0.001 g. Ovaries always presented several follicles grouped in different, discrete size classes. We considered only follicles of the largest size class from each ovary as we assumed these follicles constitute a single clutch. The ovarian follicles of the largest size class in ovaries were counted and measured under a stereomicroscope with an ocular micrometer.

We examined the relationship between the SVL and the number of ovarian follicles of the largest size class using a Pearson's test. We performed an Analysis of Variance (ANOVA) to test for differences among seasons regarding 1) ovarian mass, 2) number, and 3) mean diameter of follicles of the largest size class.

Females were divided into two categories according to ovarian mass (females with ovarian mass greater than 0.560 g and smaller than 0.560 g; this corresponds to the mid-point of the total range) in order to determine the frequency of females with the highest ovaries through time and to estimate the approximate time of clutching.

At the study site, female *E. binotatus* ranged in body size from 44.3 to 55.7 mm (= 49.8 ± 2.3 mm); ovarian mass ranged from 0.011 g to 1.128 g (= 0.389 ± 0.340 g); the number of follicles of the largest size class ranged from 20 to 67 (= 32.5 ± 10.1), and mean diameter of follicles of the largest size class ranged from 1.1 mm to 4.6 mm (= 2.6 ± 1.0 mm) (Table 1).

Correlation between the number of follicles of the largest size class and the snout–vent length of female *E. binotatus* was not significant ($r = 0.0553$; $p = 0.78$). Significant correlation between female size and clutch size is common in anurans (Kuramoto 1978; Salthe and Duellman 1973). However, Crump (1974) found this correlation in only to 26.8% of studied species in a tropical anuran community. In some species of the genus *Eleutherodactylus* there is a correlation between egg number and female size (e.g. *E. altamazonicus*, *E. lacrimosus*, and *E. lanthanites*: Crump 1974; *E. coqui*: Townsend and Stewart 1994; *E. johnstonei*: Bourne 1997; and *E. bransfordii*: Donnelly 1999) but Crump (1978) found no significant correlation in *E. conspicillatus*, *E. croceoinguinis*, *E. martiae*, *E. ockendeni*, *E. pseudoacuminatus*, and *E. variabilis*, as well *Ischnocnema quixensis*, a species that also has direct development. Species of *Eleutherodactylus* have, in general, smaller clutches with larger eggs than other genera (Salthe and Duellman 1973; Wake 1978). Probably, egg size is more important than clutch size to the reproductive success of species with direct development. Unfortunately, we did not test this hypothesis in the present study because our size data referred to follicles at different stages of development and we could not estimate the final size of eggs from our data.

There is no significant difference among wet and dry seasons, on ovarian mass ($F = 0.5379$; $df = 1, 34$; $p = 0.47$), number of follicles ($F = 2.1898$; $df = 1, 26$; $p = 0.15$), and mean diameter of follicles ($F = 0.0919$; $df = 1, 26$; $p = 0.76$). Nevertheless, females with the heaviest ovaries (ovarian mass higher than 0.560 g) were found only from September to November (Fig. 1). Furthermore, development of ovarian follicles of the largest size class (indicated by the variation in mean diameter of follicles over time; Fig.

TABLE 1. Mean, standard deviation (SD), and range of snout–vent length (SVL), ovarian mass, number, and mean diameter of follicles of the largest size class of female *Eleutherodactylus binotatus* (N = 36).

Variables	mean ± SD	range
SVL (mm)	49.8 ± 2.3	44.3–55.7
Ovarian mass (g)	0.389 ± 0.340	0.011–1.128
Number of follicles	32.5 ± 10.1	20–67
Follicles mean diam (mm)	2.6 ± 1.0	1.1–4.6

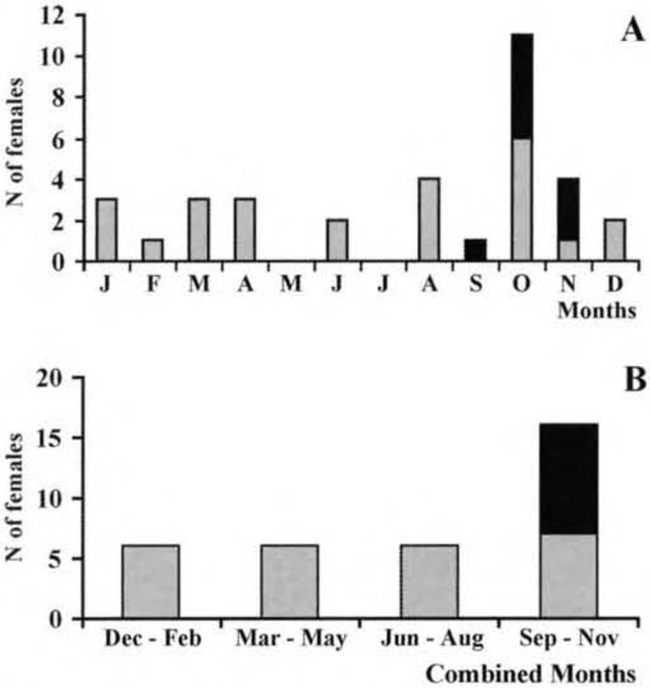

FIG. 1. Number of female *Eleutherodactylus binotatus* with ovarian mass higher than 0.560 g (black) and females with ovarian mass smaller than 0.560 g (gray), data were summed for months sampled during different years. (A) Month to month and (B) combined three-to-three months.

2) showed follicles growing during the dry season (April to September) and reaching a developmental peak at the beginning of the wet season (October to November). This peak is followed by a decrease in the mean diameter of follicles, suggestive of an end to the clutching period.

The statistical tests only compare the means among the different seasons and the graphs demonstrate that the follicles are uniformly middle sized in the whole dry season and the largest follicles are present especially at the beginning of the wet season while the smallest follicles are present at the ending of this season. Thus, despite the not significant different means, we could assume that the reproduction in *E. binotatus* is seasonal, occurring at the beginning of the wet season. This is also the time period of the highest vocalization activity of male *E. binotatus* in the same population (C. Canedo, unpubl. data).

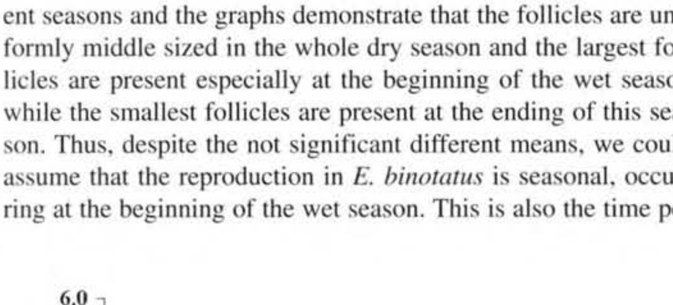

FIG. 2. Mean diameter in millimeters of ovarian follicles of the largest size class in female *Eleutherodactylus binotatus* from September 2000 (S) to March 2002 (M), presenting polynomial of third order trendline.

In the Atlantic Rainforest, in Southeastern Brazil, most anuran species reproduce only during the wet season (e.g., Pombal 1997), as we found for *E. binotatus*. However, *Eleutherodactylus* species have continuous reproduction along the year showing seasonal variation only in the frequency of reproductive activity at Amazonian Rainforest (e.g., Bourne 1997; Towsend and Stewart 1994) and Costa Rican Rainforest (Donnelly 1999).

We conclude that the studied *E. binotatus* population: 1) presents no significant correlation between number of follicles and size of females, and 2) present seasonal reproduction, occurring at the beginning of the wet season.

Longevity and Breeding Site Fidelity in the California Newt (*Taricha torosa*): A Long-Term Study Showing the Efficacy of PIT Tagging

TYLER S. WATTERS
and
LEE B. KATS
Natural Science Division, Pepperdine University
24255 Pacific Coast Hwy, Malibu, California 90263, USA
e-mail: tyler.watters@pepperdine.edu, lee.kats@pepperdine.edu

California Newts (*Taricha torosa*) inhabit the streams and surrounding terrestrial habitats along the California coast. In the winter and spring, adults migrate from terrestrial habitats to nearby streams or ponds for breeding. Few studies have examined the behavioral patterns of adult *T. torosa* in any great detail, but extensive population and migration studies on *T. rivularis* have demonstrated site fidelity and homing behavior in individuals displaced from capture locations during the breeding season (Twitty 1966). Salamanders in other families (e.g., Ambystomatidae, Plethodontidae) have been shown to possess strong breeding pond fidelity from season to season (Mathis 1989; Trenham et al. 2000), and we suspected that this characteristic exists in *T. torosa* as well.

However, demonstrating breeding site fidelity in *Taricha* is challenging experimentally, due to both their longevity and the difficulty that lies in identifying individual newts and their migrations from year to year. We examined PIT tagging as a marking method for identification in *T. torosa*. This marking technique was successful over our long-term study and enabled us to confirm breeding site fidelity in this species.

Site fidelity in newts was first verified by the use of coded toe clipping, but that technique was reliable for only a couple years following marking because newts regenerated amputated appendages and limbs (Twitty 1966). Radio transmitters, either surgically implanted or inserted into the salamanders' abdomen (Jehle 2000; Madison 1997), are not practical for long-term studies due to their limited battery life. While heat branding can be used to identify individuals years after their initial capture (Peterson et al. 1983), the use of passive integrated transponders (PIT tags) has been introduced recently as a more reliable technique (Trenham et al. 2000).

We conducted a mark-recapture study of *T. torosa* in Cold Creek, California (Los Angeles Co.), a stream located in the Santa Monica Mountains. Using permanent geographic land markers, we mapped 700 m of the stream. We surveyed this stream section annually from 1991 to 2003 and recorded the location, sex, SVL, and mass of adult newts. From 1991 to 1994, 36 adults were marked with PIT tags manufactured by AVID. Newts were anesthetized using MS222 and tags were inserted into the abdomen using a syringe. The incision was closed using New Skin® (Medtech). Each subsequent year until 2003, on several days during the breeding season, the stream was mapped and surveyed as before. Newts encountered during surveys were captured and scanned for a PIT tag. Recaptures were measured and weighed, and the distance from their first location was determined. Many individuals in this study were captured several times in a single breeding season, but only the data for their first capture of the season was included in analyses.

Through 2003, 14 of 36 (39%) tagged *T. torosa* adults were recaptured among years, up to 11 years post-tagging (mean 763 d). A few adults were captured more than once for a total of 22 recaptures. Each recapture increased in length (mean (SD): 0.12 (0.16) cm) and body mass (mean (SD): 1.11 (2.47) g) from when they had most recently been collected. Upon recapture, the mean distance between an individual's recapture site and site of initial capture was 15.5 m (SD: 30.1 m). Fourteen of the 22 total recaptures occurred at or within 10 m of an individual's original capture.

Our data demonstrate the utility of PIT tags for long term studies in newts and documentation of life history and population demography information. Our study is the first to document the potential lifespan of the California newt in the wild. One female, recovered in 2000, was originally tagged in 1991 and was last recaptured in May of 1993. Two males, originally marked in 1994, were recaptured and recorded in April of 2003, along with another male who had not been observed in the field since his original capture in 1992, 11 years earlier. Given that *Taricha* do not reach sexual maturity until at least three to four years of age in males, and slightly longer in females (Twitty 1959), the four individuals captured 9–11 years after their initial marking are likely, at minimum, 12–14 years of age.

In Southern California, the 6–12 week breeding period for *T. torosa* can last into May, but most adults leave the streams within several weeks following this period and densities drop to near zero over the course of the summer (Kats et. al 1994; Petranka 1998). Adults emerge from below ground and do not reenter streams, ponds, and reservoirs until after late Fall rains (Stebbins 2003). Our findings suggest that many individuals return to almost the exact locations within the stream among years. Exactly how *T. torosa* orient to the same location along a stream year in and year out is unknown. In *T. rivularis* and *T. granulosa*, Twitty (1959) ruled out visual navigation using landmarks and memorization of the topographical pattern of an individual's home range, and suggested navigation by a chemical mechanism. Extra-ocular magnetic orientation is now known in the red spotted newt, *Notophthalmus viridescens* (Deutschlander et. al 1999).

Acknowledgments.—We thank Tom Vandergon for his valuable field assistance, the Mountains Restoration Trust for access to Cold Creek and continuing support of stream ecology research in the Santa Monica Mountains, and the Natural Science Division at Pepperdine University for providing the equipment used in this study.

Studies analyzing anuran stomach contents are essential to determine many aspects of their ecology and natural history. Diet analysis has proven useful in many studies, including: recognition of feeding restrictions or food preferences (e.g., Parker and Goldstein 2004); examining natural history (Hamilton 1948); determining developmental stage effect on diet (Jenssen 1967); understanding niche overlap (Forstner et al. 1998; Hedeen 1972); comparing diet of sympatric species (Guidali et al. 2000); and confirming congenic/conspecific predation (Krupa 2002). Although stomach content analyses of Northern Leopard Frogs (*Rana pipiens*) and related species have been conducted (Collier et al. 1998; Knowlton 1944; Linzey 1967; Parker and Goldstein 2004), relatively no natural history data exists for this anuran in West Virginia, USA. We describe prey items and analyze feeding strategies of *R. pipiens* from one of four known breeding localities in the state.

Methods.—We captured frogs in Hoeft Marsh, an ephemeral wetland located on the western end of Greenbottom Wildlife Management Area (Cabell County, 38°35'9.4"N, 82°15'52.7"W) created by the West Virginia Division of Natural Resources in 1992 (Pauley and Barron 1995). Sampling was conducted June through November 2003, at about 2100 h and usually lasted 1–2 h. Captured frogs were stomach flushed using the method described in LeClerc and Courtois (1993). Stomach contents were preserved in 70% ethanol (v/v) and identified to class/order classification level.

Feeding strategies were determined by constructing a feeding strategy plot as described in Amundsen et al. (1996). In this method, prey-specific abundance (dependent variable) is plotted against frequency of occurrence (independent variable). Prey-specific abundance represents the percentage a prey taxon comprises only in stomachs of predators ingesting the prey taxon. Frequency of occurrence represents the frequency a particular prey item comprises out of all prey items recovered from flushing. Resulting feeding strategies can be assessed based upon location of points within the following quadrants of the feeding graph: 1) bottom left– predator population is feeding on various prey items with low frequency; 2) top right– predator population is specializing exclusively on one prey source; 3) top left– few predators out of the population are specializing upon one prey item, and; 4) bottom right– many predators out of the population are feeding on one prey item occasionally (Amundsen et al. 1996).

Results and Discussion.—Of 162 captured frogs, 64 regurgitated stomach contents during flushing. There were 216 food items identified, belonging to 19 taxonomic food groups (Table 1). Three main prey groups served as the prey base for *R. pipiens*, comprising 51.8% of total items: adult Coleoptera (24.5%), Oligochaeta (15.3%), and Hymenoptera (12.0%). Order Trichoptera represented 6% of the food items recovered, with 11 of 13 larval caddisflies procured from one frog. Additionally, one anuran, *Pseudacris c. crucifer* (Northern Spring Peeper), was recovered.

Feeding strategy analysis illustrated that *R. pipiens* was a generalistic feeder (Fig. 1), supporting the premise that they appear to be indiscriminate, opportunistic predators (Collier et al. 1998; Forstner et al. 1998; Guidali et al. 2000). There were 17 of 19 prey classes located near the bottom left of the feeding plot (Fig. 1), illustrating that numerous prey taxa were being consumed in low quantities. Also, coleopterans were being consumed occasionally by many frogs (frequency of occurrence = 0.5, Fig. 1), while trichopterans were a specialized prey taxon for a few frogs (prey specific abundance = 59, Fig. 1).

Although we did not assess prey availability, it has been suggested that availability of a particular prey item has a much greater influence than specificity in the diet of many anurans (Linzey 1967). Adult coleopterans were the major prey item for *R. pipiens*, most likely because of foraging habits for this frog. During the summer and fall months, *R. pipiens* forages in large, grassy meadows (Merrell 1977), a common habitat for many species of coleopterans. Collier et al. (1998) discovered that coleopterans were the most common food item recovered from a population of *R.*

TABLE 1. Stomach contents of 64 *Rana pipiens* in Greenbottom Wildlife Management Area, Cabell Co., West Virginia, USA.

Prey Taxon	No. Food Items (%)
Amphibia	
Anura	
Hylidae	
Pseudacris c. crucifer	1 (0.5)
Arachnida	
Araneae	11 (5.0)
Opiliones	1 (0.5)
Crustacea	
Isopoda	8 (3.8)
Diplopoda	4 (1.9)
Gastropoda	17 (7.9)
Insecta	
Coleoptera (Adult)	53 (24.5)
Coleoptera (Larvae)	13 (6.0)
Diptera (Adult)	13 (6.0)
Diptera (Larvae)	1 (0.5)
Ephemeroptera	1 (0.5)
Hemiptera	5 (2.3)
Homoptera	7 (3.2)
Hymenoptera	26 (12.0)

Lepidoptera (Larvae)	5 (2.3)
Odonata	2 (0.9)
Trichoptera	13 (6.0)
Oligochaeta	33 (15.3)

pipiens in northeastern Ohio. Linzey (1967) suggested coleopterans function as the staple food item for *R. pipiens*; frogs would feed on ephemeral insects when in abundance, but coleopterans would function as a buffer when availability of other food items declined.

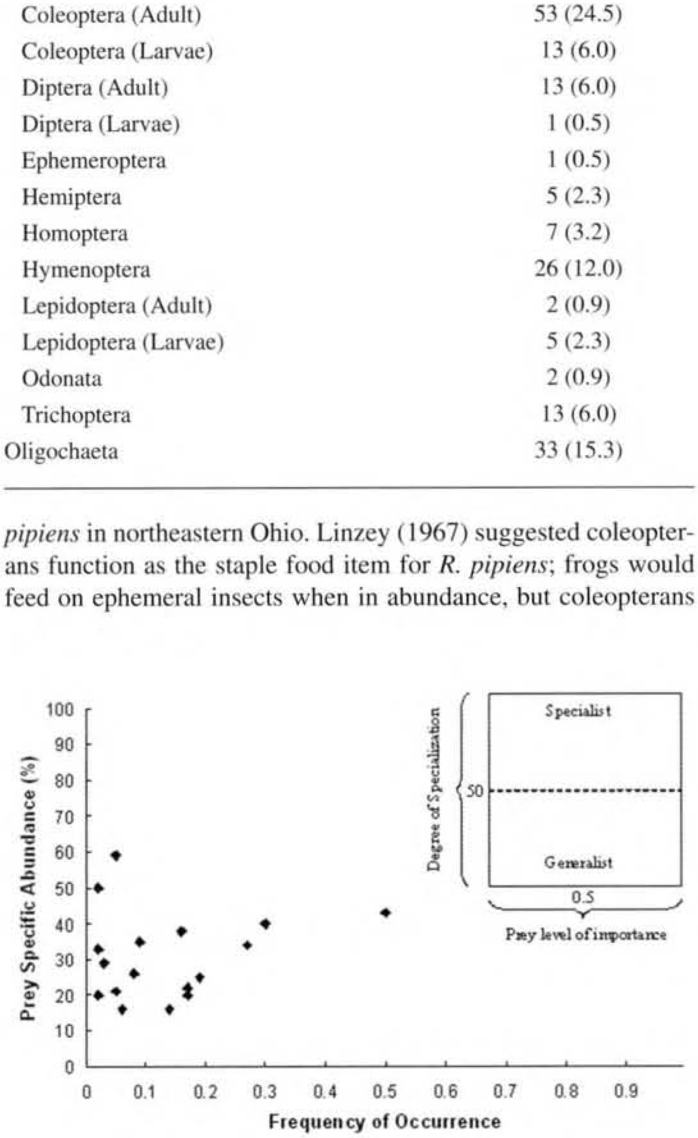

FIG. 1. Feeding strategy plot for *Rana pipiens* at Greenbottom Wildlife Management Area, Cabell Co., West Virginia, USA. Each point represents a unique prey taxon. Diagram at top right corner can be used to interpret graph results (adapted from Amundsen et al. 1996).

Prey item analysis indicates that prey specificity does not serve as a limiting factor for this species. However, availability of terrestrial habitat can be a limiting factor because *R. pipiens* requires large uncut wetland meadows for summer foraging habitat. From this, it should be a primary management concern to preserve this essential early successional wetland habitat.

Acknowledgments.—We thank C. J. Schweitzer, Y. Wang, Z. Felix, K. R. McAllister and one anonymous reviewer for their comments on previous versions of the manuscript, and Z. Loughman and L. Smith for field assistance. Permission to collect and stomach flush frogs was granted by the West Virginia Division of Natural Resources (WVDNR). This research was funded through a West Virginia Wildlife Diversity Grant supplied by the WVDNR.

Nomenclatural Notes on a Caecilian (Amphibia: Gymnophiona) Name

INDRANEIL DAS
Institute of Biodiversity and Environmental Conservation
Universiti Malaysia Sarawak, 94300, Kota Samarahan, Sarawak, Malaysia
e-mail: idas@ibec.unimas.my

Bhatta and Srinivasa (2004) described a new species of caecilian, which they named *Gegeneophis madhavai*, from "Doddinaguli locality (Mudur Village, Kundapura Taluk, Udupi District, Karnataka State"…. "situated adjacent to the Mookambika Wildlife Sanctuary in the Western Ghats" (in southwestern India).

The new species was named for four individuals who share a first name, namely, Madhava Bhat, Madhavarao Bhide, Madhava Anantha and Madhava Gadgil. The spelling of the first (= given) name of the last individual is, in fact, Madhav, a contemporary north Indian version of the spelling. The name is derived from the Sanskrit, meaning vernal, originating from the name Madhu, a legendary king, whose most famous descendant is Krishna, a Hindu god (see Hanks and Hodges 1990).

According to Article 32.5 of the International Code of Zoological Nomenclature (International Commission of Zoological Nomenclature 1999), in case of clear inadvertent error in the formation of a new nomen, correction of the nomen is possible (see Bauer and Das 2000 and Michels and Bauer 2004, for some recent examples of corrections of original nomen). Indeed, Article 34.2 states that errors in spelling of the endings must be corrected. In the present case, because the new caecilian is named for more than a single individual, the termination of the species nomen should be *-orum*. The species nomen of the south Indian caecilian described by Bhatta and Srinivasa (2004) is here emended to *Gegeneophis madhavaorum*.

Under Article 33.2.2, the corrected nomen retains the original authorship and date. The valid name of the new south Indian caecilian is therefore *Gegeneophis madhavaorum* Bhatta and Srinivasa, 2004.

Acknowledgments.—I thank the Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak for supporting my research and Hobart Muir Smith and an anonymous reviewer for comments on a draft manuscript.

A Male Hybrid from *Aspidoscelis sonorae* (Parthenogenetic) and *A. burti stictogramma* (Bisexual): Squamata, Teiidae

HARRY L. TAYLOR
Department of Biology (D-8), Regis University
Denver, Colorado 80221-1099, USA
e-mail: htaylor@regis.edu

Although *Aspidoscelis burti stictogramma* (Giant Spotted Whiptail) is remarkable for its past participation in hybridizations contributing to the origins of six triploid parthenogenetic species: *A. exsanguis*, *A. flagellicauda*, *A. opatae*, *A. sonorae*, *A. uniparens*, and *A. velox* (Reeder et al. 2002; Wright 1993), contemporary hybridization by *A. burti stictogramma* is undocumented. Participation in hybridization events by the six parthenogenetic species ranges from rare to absent, with the frequency determined by opportunity and ecological context (Taylor et al. 2001; Walker et al. 1989). Rare hybridization is exemplified by *A. exsanguis*, *A. sonorae*, *A. uniparens*, and *A. velox* (Cuellar and McKinney 1976; Hardy and Cole 1998; Neaves 1971; Taylor et al. 1989), and hybridization by *A. flagellicauda* and *A. opatae* is unknown—because contact with bisexual congeners is limited for the former (Wright and Lowe 1968) and absent for the latter (Wright 1967). The objective of this report is to describe the first known hybrid between *A. sonorae* and *A. burti stictogramma*.

On 12 June 1972, P. Casella collected a female *A. burti stictogramma* (119 mm snout–vent length [SVL]; Regis University [RU] 7232) and four specimens that I identified as parthenogenetic *A. sonorae* (RU 7233–7236). These five specimens were collected in a lush, Lower Sonoran Zone habitat (Lowe 1964, his Fig. 6) on a lower slope of the Santa Catalina Mountains (accessed from the Mount Lemmon Highway) east of Tucson, Arizona. In 1992, I dissected each specimen for evidence of egg clutches and was surprised to find normal appearing testes and vasa deferentia in RU 7234, a specimen of 70 mm SVL (Fig. 1). Its testes dimensions (left: 5.2×3.0 mm, right: 5.5×3.2 mm) were comparable in relative size to the testes (left: 5.4×4.4 mm, right: 6.5×4.0) of an adult male *A. burti stictogramma* of 87 mm SVL (RU 95170, Fig. 1) collected on 9 July 1995 from a different locality. The ratio of testis width to SVL for RU 95170 was within the 95% confidence interval expected for males of *A. burti stictogramma* collected in July (Goldberg 1987). Although RU 95170 (87 mm SVL) was likely reproductively mature, it still expressed the juvenile color pattern of *A. burti stictogramma*—pale gray, intact stripes sharply contrasting with the adjacent dark brown fields, each field supporting small tan spots, and a subdued dorsal pattern on the legs (Fig. 1). In contrast, the representative of *A. burti stictogramma* collected at the hybridization site (RU 7232, 119 mm SVL) had completed the ontogenetic transition—fragmentation of primary stripes into large spots, enlargement and lightening of dark field spots, and establishment of a high density of prominent pale spots on the dorsal surfaces of the legs—to a final color pattern characterized by spots rather than by stripes.

There were two reasons why RU 7234 could not be reassigned to *A. burti stictogramma*. First, the male had only 70 granular scales

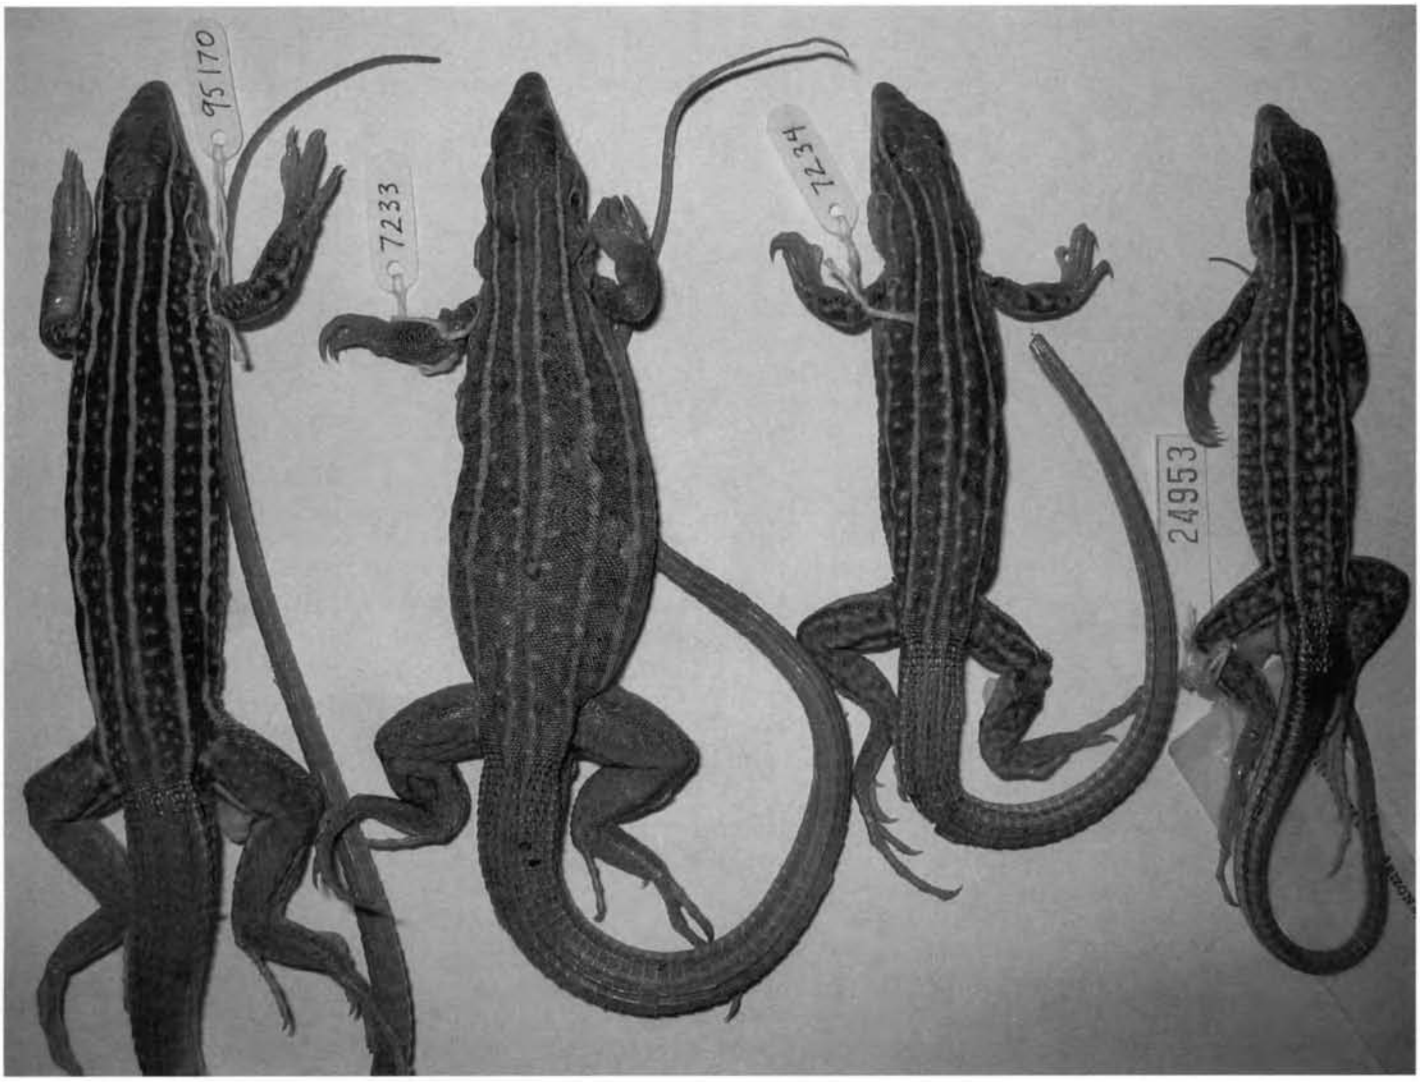

FIG. 1. Left to right: *Aspidoscelis burti stictogramma* (RU 95170: male, 87 mm SVL) with juvenile color pattern; *Aspidoscelis sonorae* (RU 7233: 84 mm SVL); *Aspidoscelis sonorae* × *Aspidoscelis burti stictogramma* (RU 7234: male, 70 mm SVL); *Aspidoscelis sonorae* × *Aspidoscelis tigris punctilinealis* (UAZ 24953: male, 63 mm SVL).

around midbody (GAB), whereas *A burti stictogramma* is characterized by GAB counts > 97 (Duellman and Zweifel 1962; Lowe 1956). Second, the SVL of 70 mm is well below the minimum size of reproductive maturity for male *A. burti stictogramma* (87 mm SVL) as determined histologically (Goldberg 1987). Thus, the only possible mode of origin for a male resembling *A. sonorae* of comparable size in color pattern and having a GAB count within the range of variation for this species (HLT, unpubl. data) was by fertilization of an unreduced egg ($3n = 69$) of triploid *A. sonorae* by a spermatozoan ($n = 23$) carrying a Y-chromosome from a bisexual species (Cole et al. 1969; Taylor et al. 2001). The only bisexual congener actually observed in syntopy with the hybrid and *A. sonorae* was *A. burti stictogramma*; however, there were two reasons to also consider *A. tigris punctilinealis* for the male parent of the hybrid. First, adequate sampling was not possible to rule out the possibility that *A. tigris punctilinealis*, well represented at lower elevations, was not also present at the collecting site. Second, *A. sonorae* is known to hybridize with *A. tigris punctilinealis*, and two *A. sonorae* × *A. tigris punctilinealis* hybrids (University of Arizona [UAZ] 24953 and 24954) described by Lowe et al.

TABLE 1. Quantitative differences among a putative *Aspidoscelis sonorae* × *A. burti stictogramma* hybrid (S × S) and two *A. sonorae* × *A. tigris punctilinealis* hybrids (S × P). See Appendix I for character definitions.

Specimen	GAB	FP	COS	SDL	ILS	LSG	PV	SVL
RU 7234 (S × S)	70	43	14	34	32	47	3	70
UAZ 24953 (S × P)	74	44	14	35	28	31	7	63
UAZ 24954 (S × P)	70	42	12	—*	21	27	3	64

*Both feet are missing from this specimen.

TABLE 2. Color and pattern differences between hybrids derived from *Aspidoscelis sonorae* females and *A. burti stictogramma* and *A. tigris punctilinealis* males.

Character	*A. sonorae* × *A. burti stictogramma* (RU 7234)	*A. sonorae* × *A. tigris punctilinealis* (UAZ 24953 and 24954)
Dark field color	brown	dark gray
Stripe color	cream	pale gray
Ventral color	cream	pale gray[1]
Dark field spots	few (small) indistinct; in dorsolateral and upper lateral dark fields	numerous (large) distinct; in dorsolateral and upper lateral dark fields
Paravertebral stripe	intact (with superimposed light spots)	disrupted (without superimposed light spots)[2]

[1]Ventral melanism, as expressed in *A. tigris punctilinealis*, is lacking.

[2]Pale spots may fuse with lateral margins of paravertebral stripes to produce irregular borders.

(1970) were available for comparisons to RU 7234. Although the male parents of RU 7234 and the two UAZ hybrids were of different taxa, all three specimens had enlarged postantebrachial scales, thereby resembling *A. sonorae* (and *A. burti stictogramma*), rather than *A. tigris punctilinealis*, in this character. Additional similarities between RU 7234 and the *A. sonorae* × *A. tigris punctilinealis* hybrids included six of seven meristic characters, with only the sum of the lateral supraocular granules on both sides of the head (LSG) suggesting a possible significant difference (Table 1). These scalation similarities among the three hybrids presumably reflect the genomic contribution to each from triploid *A. sonorae*. Nevertheless, five color and color-pattern differences between RU 7234 and the two UAZ hybrids identify *A. burti stictogramma*, rather than *A. tigris punctilinealis*, as the paternal parent of RU 7234 (Table 2, Fig. 1). Two character states, intact paravertebral stripes in *A. sonorae* × *A. burti stictogramma* and disrupted paravertebral stripes in *A. sonorae* × *A. tigris punctilinealis*, express phenotypic differences in the paternal taxa (see Appendix I for stripe descriptions). Disrupted paravertebral stripes are also exhibited by AMNH R-122989, a sterile female hybrid produced by housing *A. sonorae* with *A. marmorata* (= *A. tigris marmorata*) in the laboratory, which also inherited paravertebral stripe fragmentation from its male parent (Hardy and Cole 1998, their Fig. 1). There are, however, important color-pattern differences between AMNH R-122989 and the RU and UAZ hybrids. Some differences are related to age of the individual, but other differences are based on two different color-pattern classes of *A. sonorae* involved in the hybridizations. Two of several pattern classes of *A. sonorae* are illustrated, but not characterized, by Dessauer and Cole (1989, their Figs. 2D and F). The *A. sonorae* mother of AMNH R-122989 has white spots superimposed on paravertebral, dorsolateral, and lateral stripes, but spots are absent from her dark fields (Hardy and Cole 1998, their Fig. 1). In contrast, the *A. sonorae* pattern class involved in the production of RU 7234 and UAZ 24953–54 has spots in the dark fields as well as on the dorsal stripes (Fig. 1).

The identification of *A. burti stictogramma* as the male parent of RU 7234 might seem questionable because of the large size attained in this taxon and the striking difference in body mass eventually obtained by individuals of *A. burti stictogramma* and *A. sonorae*. However, reproductive maturity develops in male *A. burti stictogramma* at 87 mm SVL (Goldberg 1987), long before this size differential appears, and, because individuals of *A. sonorae* can attain a SVL > 87 mm (Taylor and Caraveo 2003), there is a size range of physical compatibility (Fig. 1). An additional factor seeming to weaken the candidacy of *A. burti stictogramma* as the paternal taxon of RU 7234 would be the low GAB count of 70 expressed by RU 7234. The argument derives from the accumulation of *A. burti stictogramma* genomes in the production of such a hybrid. The two-step hybridization sequence that led to the origin of *A. sonorae* (Reeder et al. 2002; Wright 1993) brought together two genomes from *A. burti stictogramma*. Step one was a cross between *A. inornata* and *A. burti stictogramma* to produce a parthenogenetic diploid. Step two was the mating of this diploid intermediate with *A. burti stictogramma* to produce the triploid, parthenogenetic hybrid from which *A. sonorae* originated. Therefore, if *A. burti stictogramma* is the male parental taxon of RU 7234, this hybrid should have three genomes ultimately traceable to *A. burti stictogramma*, a taxon that has GAB counts > 97. This difference between genetic endowment and phenotypic expression suggests that the single genome of *A. inornata* (GAB counts 55–72; Wright and Lowe 1965) carried by *A. sonorae* and the hybrids exerts a disproportionate effect on the expression of this character.

Acknowledgments.—I extend my appreciation to G. Bradley for a loan of UAZ 24953–54. I thank two reviewers and R. Espinoza, whose comments and suggestions improved the manuscript. Fieldwork was facilitated by a Regis University TSSC summer research grant.

APPENDIX I

Characters

GAB = number of granular dorsal scales in a single row around midbody (the 15th ventral scale posterior to the axilla established the point for beginning this count); FP = sum of femoral pores on both thighs; COS = bilateral total of circumorbital scales; SDL = number of subdigital lamellae on the fourth toe of one foot (right was chosen unless damaged); ILS = all interlabial scales between the lower labials and sublabials counted anterior to the suture line between 5th and 6th lower labials; LSG = sum of lateral supraocular granules on both sides of the head (the count includes all scales between the supraoculars and superciliaries, anterior to the suture line between the third and fourth supraoculars); PV = number of scales between paravertebral stripes at midbody; SVL = length of body from tip of snout to posterior edge of precloacal scales (in mm). PARAVERTEBRAL STRIPES = the most dorsal pair of pale stripes extending from each large parietal scale on the head to base of tail; LATERAL STRIPES = the most ventral pair of pale stripes extending from below the eye, across the top of the ear opening to the thigh, then continuing posterior to the thigh onto the base of the tail; DOSOLATERAL STRIPES = a pair of pale stripes located between paravertebral and lateral stripes, extending from the superciliaries just dorsal to the eye onto the base of the tail; DARK FIELDS = longitudinal dark areas separating pale stripes.

**Present address: Colorado Division of Wildlife, 151 E 16th Street Durango, Colorado 81301, USA*
e-mail: andy.holland@state.co.us

The distribution and abundance of the southern Rocky Mountain population of Boreal Toads (*Bufo boreas boreas*) have dramatically declined (Carey 1993; Corn et al. 1989; Loeffler 1998). *Bufo boreas* is currently listed as endangered in the state of Colorado. Improved understanding of breeding habitat preferences would be useful when surveying new habitats, evaluating potential translocation sites and constructing wetlands for *B. boreas*.

Bufo boreas appears to be a generalist in terms of the terrestrial habitats that it occupies but has more specialized breeding habitat requirements. In Colorado, *B. boreas* occurs primarily between 2250 m and 3600 m elevation in Lodgepole Pine (*Pinus contorta*), spruce (*Picea* sp.), Subalpine Fir (*Abies lasiocarpa*), and alpine meadows (Loeffler 1998). *Bufo boreas* breeds in the margins of ponds and lakes in May and June. Common types of breeding sites in Colorado are American Beaver (*Castor canadensis*) ponds, high elevation lakes and ponds, high elevation meadow ponds, and human excavated wetlands. Ideal *B. boreas* breeding sites presumably contain still water, very shallow margins and persistent water levels. Egg masses typically are deposited communally in the shallowest available areas of the breeding site (Livo 1999). Although *B. boreas* oviposition area characteristics have been described qualitatively (Livo 1999; Loeffler 2000), we are unaware of quantitative descriptions. Holland (2002) compared mean July water temperature, variance in water temperature, pond persistence, bank slope of the pond, and surface area in breeding and adjacent nonbreeding ponds. Detecting differences between breeding and nonbreeding sites proved difficult because of breeding site habitat variation. However, very shallow water was consistently selected for egg deposition. Our study objective was to further quantify characteristics at egg deposition areas throughout Colorado.

Methods.—We identified 33 breeding sites for southern Rocky Mountain *B. boreas* that had at least one egg mass for four consecutive years (1997–2000), and randomly selected 18 of these for study in 2000.

Study sites were in Chaffee, Clear Creek, Summit, Eagle, Routt, and Gunnison counties, Colorado, and ranged from 2542 m to 3487 m elevation. Sites were primarily in wet meadows in subalpine communities dominated by spruce-fir. *Salix* spp. and *Carex* spp. usually were found in riparian areas surrounding sites. Study

sites were visited from breeding through metamorphosis and comprised nine beaver ponds, one high elevation lake, three high elevation meadow ponds, and five sites of anthropogenic origin.

Water depth at the center of every identifiable egg mass was measured to estimate mean depth selected for oviposition per site. Depths were not measured unless *B. boreas* was still breeding at the site to ensure that water levels did not fluctuate between breeding and measurement. Amount of shallows present, and consequently potential breeding habitat, was quantified by measuring the length of shoreline that had water ≤ 10 cm depth, measured 30 cm from the margin for consistency. Ten centimeters was chosen because this was the maximum egg deposition depth observed in 1999 (Holland, unpubl. data). Finally, bank slope was evaluated by measuring depths at 0.30 m, 1 m, and 5 m from the margin on 10 transects in the egg deposition area at each site. Linear regression was used to examine depth as a function of distance from shore by site.

Results.—Breeding was initiated between 5 May and 9 June 2000. Mean number of egg masses deposited was 5.7 (S.E. = 0.9, range = 1–13, N = 18). Depths of 38 egg masses were measured at 10 sites while egg deposition was still occurring. Mean depth of egg masses by site was 6.1 cm (S.E. = 0.6, range = 3.0–9.8 cm, N = 10). Metamorphosis was initiated at 14 sites between 21 July and 29 August 2000.

Mean length of shallow shoreline was 52.1 m (S.E. = 9.9, range = 10–190 m, N = 18). The mean slope of the oviposition area bank was 0.07 (range = 0.02–0.12, N = 17) or a 7-cm increase in depth for every 1-m increase in distance from shore. Desiccation occurred prior to measurement at one site.

Discussion.—Our data support the presence of very shallow water as a cue for *B. boreas* oviposition in Colorado. A suitable site also appeared to have at least one gradually sloping bank with water ≤ 10 cm deep during the breeding season. The maximum mean egg mass depth for a site was 9.8 cm. This depth is consistent with those observed in 1999 and might be considered the maximum depth that southern Rocky Mountain *B. boreas* deposit their eggs. In contrast, Olson (1989) reported depths of oviposition for Oregon *B. boreas* between 5 and 25 cm, and on vegetation in up to 2 m of water at one site. In Colorado, eggs seem to be deposited in shallows despite the increased potential for egg mortality that exists as a result of desiccation and freezing (Livo 1999). Shallows that allow for elevated water temperatures on sunny days (Barandun and Reyer 1997) could be especially important to *B. boreas* because of cold water temperatures at high elevation.

Gradually sloping banks ensure that suitable breeding habitat exists at a variety of water levels. Gradually sloping breeding site banks also were found to be an important factor in predicting use by Natter Jack Toads (*Bufo calamita*) (Banks and Beebee 1987). Observed mean bank slope of 7% is steeper than would be expected given the fact that *B. boreas* appears unwilling to deposit eggs much deeper than 10 cm. The steep bank slopes of many study sites limit egg deposition to shallows very near shore, these shallows are not present in all Colorado mountain wetlands.

Mean length of shoreline in breeding sites with water depths ≤ 10 cm was 52.1 m. Size and suitability of ovipositioning areas may be more attractive to amphibians than actual breeding site area (Reading et al. 1991). Loman (1988) found that Common Frog *(Rana temporaria)* breeding sites were best predicted by the amount of shallows. However, *B. boreas* communal breeding behavior may not require large egg deposition areas.

These breeding habitat characteristics will be useful for evaluating breeding habitat suitability, potential translocation sites and when constructing wetlands for *B. boreas*. Potential translocations sites also should be examined in August to ensure that water retention at breeding sites is sufficient to allow completion of the larval period. In addition, a deeper water area may be necessary to provide tadpoles with a night refuge of warmer water (Beiswenger 1977; Bradford 1984). An old, but active, American Beaver pond complex seems an ideal model for a breeding site because shallow, eutrophic ponds exist in concert with water level maintenance by beaver. Future evaluation of how novel translocation sites and human excavated wetlands with different shoreline characteristics are used by breeding adults will provide additional information on how *B. boreas* select sites for egg deposition.

Acknowledgments.—Funding for this project was provided by the Colorado Division of Wildlife and Great Outdoors Colorado Trust Fund. Alan Covich, Beatrice Van Horne, and Bruce Wunder provided advice and ideas that greatly improved the project. Special thanks to Lauren Livo, Brad Lambert, and Craig Fetkavich for their advice and help in the field. Thanks also to Lauren Livo for commenting on earlier drafts of the manuscript. We also thank Deanna Olson, Paul Thompson, and 3 anonymous reviewers for their comments. This research was approved by the Colorado State University Animal Care and Use Committee (Protocol 00-108A-01).

Amphibians are regarded as highly sensitive to environmental changes. Their biological features make them vulnerable to several kinds of disturbances, including habitat modification (especially changes in the hydrology), climatic changes (especially rainfall reductions), and water pollution, including pesticides, sewage and acidic rains. Several authors have pointed out a global decrease in amphibian abundance and diversity, which can be linked to global climatic changes and/or to habitat modification, among other factors (Heyer et al. 1988; Houlahan et al. 2000; Young et al. 2001), although it may be difficult to distinguish clearly between human impacts and natural fluctuations (Pechmann et al. 1991).

The Atlantic Forest in eastern Brazil supports an extremely high diversity of anurans (Weygoldt 1989), has been dramatically reduced and fragmented during the last few centuries (Dean 1996). Population decreases and local extinctions of anuran populations have already been recorded in the Atlantic Forest (Heyer et al. 1988; Weygoldt 1989). Such changes may happen very quickly; Weygoldt (1989) reported that several species that were abundant in 1979 disappeared within ten years in Estação Biológica de Boracéia, State of São Paulo, Brazil. However, in order to determine whether these patterns were caused by human impacts, it is necessary to have a more detailed knowledge on processes involved in the natural population dynamics of Atlantic Forest anurans. An important feature of the demography of many anuran species is that males gather in reproductive aggregations where they call to attract females. The present study had the goal of studying seasonal variation in numbers of calling males in a reproductive aggregation of tree frogs *Scinax albicans* (Bokermann 1967) in a mountain stream within the Atlantic Forest in Southeastern Brazil.

Material and Methods.—The aggregation studied was located at a small stream tributary to Paquequer River, Parque Nacional da Serra dos Órgãos, municipality of Teresópolis, State of Rio de Janeiro, southeastern Brazil (22°26'57"S and 47°00'52"W). Parque Nacional da Serra dos Orgãos is located across a mountain range with steeply sloping terrain. The stream is located at an elevation of 1165 m. The climate in the study area is warm tropical. According to the Instituto Nacional de Meteorologia (INEMET) the average annual temperature was 20.5°C and average annual precipitation was 1569 mm during the period 1998–2002. The study period (from September 2001 to July 2002) present average temperature 20.9°C and average precipitation 1626 mm. The rainfall in the study period followed the usual seasonality of the area, as most was concentrated in a wet season from November 2001 to April 2002 (precipitation in these six months, 1349 mm). The study also included parts of two dry seasons, from September to October 2001, and from May to July 2002 (total precipitation in these five months 277 mm; Fig. 1). The sampled stream flows across steeply sloped terrain until reaching the Paquequer River. The substrate is formed of rocks and the water has little turbidity. Rapids alternate with pools. The depth of the pools varied from 12 to 60 cm. The riparian vegetation is Atlantic Forest, with Leguminosae, Begoniaceae, Mirtaceae, Meliacae, Piperaceae, Melostomataceae, Poaceae, Areceae, and Polypodiaceae among the most common families.

The aggregation was monitored through sampling sessions twice a month, from September 2001 to July 2002. In the data analysis, however, we used only sampling sessions where calling males were found (fifteen sessions), as aggregation size could not be estimated for the remaining sessions. Each session lasted an average of three consecutive nights. The sampling area corresponded to a strip of land along the stream margins where male frogs were found calling. The length of the strip was 16 m and its maximum width was 3 m. No calling males were found beyond the extremes of this strip, although there was no obvious habitat change. The frogs were localized acoustically and then captured by hand. The frogs were individually marked by toe-clipping, following the method of Martof (1953). After marking and recording the data (sex, snout-vent length, point of capture, and individual number), each individual was released at the place it had been captured.

Aggregation size (AS), loss rates, and recruitment of calling males to the aggregation were estimated using the Jolly-Seber method (Seber 1982). Each sampling session as a whole was regarded as a "capture" for Jolly-Seber analysis. As frogs were located acoustically, AS estimated by Jolly-Seber should reflect the number of males taking part in the reproductive aggregation, rather than the total population of males using the area. Loss rates (L) were calculated from Jolly-Seber's estimated survival rates (S), using the formula $L = 1 - S$. In our results mortality cannot be separated from dispersal; therefore, we preferred to use "loss" instead of mortality, and Jolly-Seber's survival is here regarded as an estimate of the proportion of males remaining in the aggrega-

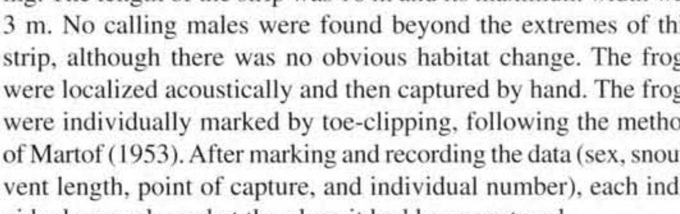

Fig. 1. Variations in rainfall and air temperature of the study area, Parque Nacional da Serra dos Órgãos, Teresópolis, from September 2001 to July 2002 (bars – monthly rainfall, line – monthly average temperatures).

tion between consecutive sampling sessions. Although the interval among the samplings were not constant, survival rates (and consequently loss rates) were standardized to 30-day intervals using logarithm transformations as suggested by Fernandez (1995).

Aggregation size (dependent variable) was related either to loss rates or to recruitment (independent variable) using simple linear regression (Zar 1999). Loss rates and recruitment (used now, one at a time, as the dependent variable) were also related to rainfall (independent variable), by single linear regressions (Zar 1999). The regressions between demographic rates and rainfall were carried out using the rainfall recorded: 1) during the days that formed each sampling session; 2) in the day before each session; 3) in the five previous days; 4) in the 15 previous days (corresponding roughly—as the intervals were not exactly equal—to the interval between sessions). The last three analyses aimed to look for delayed effects of rainfall on the processes (recruitment and losses) which affected the number of calling males in the aggregation.

Results.—Some sampling nights (including three whole sampling sessions) did not provide captures as no reproductive activity was recorded in those nights. From the remaining 15 sampling sessions, useful data could be obtained from a total of 28 nights. In total, 220 captures of 41 male individuals of *S. albicans* were obtained.

The average estimated aggregation size was 23.34 males. Variation along the study period was small (SD = 7.63, CV = 0.32). Permanence of *S. albicans* males in the aggregation was high. Loss rates were low through most of the study period, except for September 2001, March and May 2002 (Table 1; Fig. 2). Recruitment of males was quite variable, with peaks at the months of October 2001, January, May, and June 2002 (Table 1; Fig. 2).

In the regressions among demographic parameters, recruitment explained nearly 89% of the variation in the number of calling males in the aggregation ($r^2 = 0.8878$); the regression between these two variables was highly significant ($F_{1,10} = 79.16$, $P < 0.0001$). On the other hand, there was no significant regression between loss rates and number of males in the aggregation ($F_{1,11} = 0.61$, $P = 0.451$).

There was no significant relationship between either the loss rates or the recruitment and the rainfall between sampling sessions (recruitment, $F_{1,10} = 0.0163$, $P = 0.9009$; loss, $F_{1,11} = 9093$, $P = 0.3608$). The relationship remained non-significant either using the day before each session (recruitment, $F_{1,10} = 0.9979$, $P = 0.3414$; loss, $F_{1,10} = 0.3188$, $P = 0.5837$), five previous days (recruitment, $F_{1,10} = 0.1454$, $P = 0.7110$; loss, $F_{1,11} = 1.908$, $P = 0.1946$) or 15 previous days (recruitment, $F_{1,10} = 0.9733$, $P = 0.3471$; loss, $F_{1,11} = 0.0580$, $P = 0.8141$).

Discussion.—The modest variation in aggregation size along the study was explained better by the recruitment of new males to the aggregation than by their losses, which were low most of the time. Recruitment showed an irregular pattern, as peaks were recorded in different months without any clear seasonality. If aggregation size reflects the size of the whole *S. albicans* population in the area, a relationship of recruitment with rainfall would be expected – as rainfall usually is related with abundance of arthropods, which are important resources for anurans. However, no such relationship was found. Indeed, one of the peaks of recruitment was found in June 2002, one of the few months with water deficit along the study (Fig. 1). Actually, one could also expect a negative relationship of *S. albicans* recruitment and/or permanence with rainfall at least in short term—during the sampling session or in the day before, as in nights of strong rains or preceded by strong rains the frogs had decreased reproductive activity (Nascimento 2003). The strong currents in the stream these nights make the environment

unsuitable for oviposition by *S. albicans*. However, no significant negative relationship was recorded.

The patterns found show aggregation size to be remarkably constant by the standards of any vertebrate populations. The permanence of males in aggregation was high, and the little variation in aggregation size was explained by variations in the numbers of males entering the aggregation each month. The possibilility that aggregation size could be used as in index to population size is jeopardized by its high constancy and lack of relationship with rainfall patterns. Possibly aggregation size is rather controlled by social factors regulating the number of males calling at a time in any given place.

Acknowledgments.—We thank IBAMA (Instituto Brasileiro de Meio Ambiente e Recursos Naturais Renováveis) for allowing the work at Parque Nacional da Serra dos Orgãos; Instituto Nacional de Meteorologia (INEMET) for climatic data; Sergio Potsch de Carvalho e Silva for teaching on amphibians, for logistic support and co-supervising DN's MSc dissertation; the several colleagues, especially Fábio Nascimento, who helped in field work; Rômulo Barroso for company in all field work and discussions throughout the study; José P. Pombal Jr., William Magnusson, Jon Loman, Monique Van Sluys, Ronaldo Fernandes, Gunther Koehler and an anonymous referee for very useful comments on the manuscript; Jorge Luiz do Nascimento for ideas in this study and for financial support.

Abundance and Biomass of Twelve Species of Snakes Native to Northeastern Kansas

HENRY S. FITCH
University of Kansas Fitch Natural History Reservation
2060 East 1600 Road, Lawrence, Kansas 66044, USA

and

ALICE F. ECHELLE
Department of Zoology, Oklahoma State University
Stillwater, Oklahoma 74078, USA
e-mail: aechelle@juno.com

The purposes of this paper are to examine abundance and biomass estimates of the dozen most abundant snake species in our area of northeastern Kansas, and to relate these numbers to information reported in the literature. Hirth and King (1968) stated, "In spite of all the current interest in ecosystem ecology there is still a dearth of information concerning biomass densities of snakes in various habitats." Except for a few studies (e.g., Bonnet et al. 2002; Godley 1980; Hirth and King 1968; Reichenbach and Dalrymple 1986; Winne et al. 2005), the situation does not seem to have changed appreciably in the last 37 years.

Methods and Study Area

Snakes have been studied for the past 56 years on Kansas University's Natural History Reservation (FNHR) following establishment of the area as a reserve. Although protected from anthropogenic alterations, the area has undergone continual and progressive change due to natural ecological succession (Fitch 1999; Fitch et al. 1984, 2001, 2003b). The closing in of forest and elimination of open places associated with agriculture and grazing has been unfavorable for snakes. Several of the species have disappeared from this 239-hectare tract, and almost all species have been drastically reduced (Fitch 1999). The adjoining Nelson Environmental Study Area (NESA), acquired by the University in 1970, has provided a contrast to FNHR in terms of habitat stability. Invasion of woody vegetation is prevented on NESA by the regular mowing of blocks of former pasture and cultivated land, and as a result, existing snake populations resemble those found on FNHR in earlier stages of succession (Fitch 1999).

Sampling areas (House Field, Quarry Field, etc.) are described by Fitch (1999). Of the 12 censuses reported here, eight were from FNHR and were done in the earlier years of study (before 1979) except that for *Thamnophis sirtalis*. Of the remaining four species, *Carphophis vermis* was censused by Clark (1970) on private property adjoining FNHR and three, *Lampropeltis triangulum*, *L. calligaster*, and *Coluber constrictor*, were censused post-1990 on NESA.

Unless otherwise noted, density estimates are based on field records and censuses originally published in Fitch (1999) except for Clark's (1970) *Carphophis* figures. Mark-recapture records and the Petersen Index were the bases for the abundance estimates for most species, including *Agkistrodon contortrix* (Copperhead), *Carphophis vermis* (Western Wormsnake), *Coluber constrictor* (Racer), *Crotalus horridus* (Timber Rattlesnake), *Diadophis*

cit.). Here, I report a reproductive event in *Uromacerina ricardinii*, a diurnal and arboreal snake occurring principally in Atlantic Forest in southeastern Brazil (Amaral 1978. Serpentes do Brasil. Melhoramentos Univ. São Paulo, Brazil. 246 pp.; Cunha and Nascimento 1982. Bol. Mus. Par. Emilio Goeldi, n.s. Zool. 113:1–9).

A gravid female (522 mm SVL, 415 mm tail, 28.5 g) was found on 9 November 2003 in Atlantic forest near Núcleo Santa Virginia (Parque Estadual da Serra do Mar, São Paulo, Brazil; 23°20'S, 45°08'W; ca. 810 m elev.) and maintained in captivity. On 12 November 2003, she laid five eggs between 2300–2400 h. These eggs averaged 24.8 ± 2.4 mm in length (range 22.4–28.8 mm), 10.2 ± 0.3 mm in diameter (9.9–10.8) mm, and 1.6 ± 0.1 g (1.5–1.8 g). Total clutch mass was 8.1 g and the female weighed 20 g after ovipositing, resulting in a relative clutch mass (RCM) of 40.5%. Relative reproductive effort (Lemen and Voris 1981. J. Anim. Ecol. 50:89–101), obtained by dividing the total clutch mass by female pre-oviposition mass, is 28.4%. The eggs were incubated in moist vermiculite (22–28°C). Hatching occurred between 25–28 January 2004 and the neonates were immediately weighed and measured. Four neonates (136.7 ± 4.7 mm SVL, range 131–142 mm; 103.5 ± 3.7 mm tail length, 102–105 mm; 1.12 ± 0.01 g, 1.12–1.14 g) hatched after an incubation period of 84–87 days. After twenty days the fifth egg was opened and a dead embryo was discovered. The female died seven days after ovipositing and was vouchered in the Instituto Butantan collection (IB69144).

Morato and Bernils (1989. Acta Biol. Leopol. 11:273–278) report a small clutch (three eggs) with oviposition in November and hatching in the end of January. Marques (1998, *op. cit.*) reported a gravid female with six eggs in November and two vitellogenic (follicles > 5 mm) females in August. Collectively, these observations suggest a seasonal reproductive cycle for *U. ricardinii*, with oviposition in the beginning of the rainy season (November–December) and hatching occurring in the end of the rainy season (February–March). *Uromacerina ricardinii* has the slender body typical of arboreal species but the RCM seems similar to that of terrestrial colubrids (Seigel and Ford 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 184–209. Macmillan Publ. Co., New York).

I thank O. A. V. Marques and M. T. Hartmann for reviews and FAPESP and CNPq for financial support.

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother 2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. SSAR Herpetol. Circ. 29:1–82, available online at <http://herplit.com/SSAR/circulars/HC29/Crother.html>; for Mexico as it appears in Liner 1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*. Herpetol. Circ. 23:1–113), LOCALITY (use metric for distances and give precise locality data), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author—curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Leviton et al. 1985, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology*, Copeia 1985[3]:802–832) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief), SUBMITTED BY (give name and address in full—spell out state or province names—no abbreviations).

Some further comments. This geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens which have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality color slide or photograph may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Color slides and photographs *must* be deposited in a university or museum collection along with complete locality data, and the color slide catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary) to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **Alan M. Richmond** (USA & Canadian records only); **Jerry D. Johnson** (Mexico and Central America, including the Caribbean Basin); **Indraneil Das** (all Old World records); or **Gustavo J. Scrocchi** (South American records). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Schmitz, A., and T. Ziegler. 2003. Geographic distribution. *Sphenomorphus rufocaudatus*. Herpetol. Rev. 34:385.

CAUDATA

AMBYSTOMA MACULATUM. (Spotted Salamander). USA. TENNESSEE: Fayette Co.: Wolf River Wildlife Management Area managed by the Tennessee Wildlife Resources Agency located in the SE Moscow Quad (35.029000° N., -89.265350° W; NAD 83). 06 January 2005. Brandon Wear of the Tennessee Wildlife Resources Agency. Austin Peay State University Museum of Zoology, APSU 18051 (color photo). Verified by A. Floyd Scott. One specimen found in a drift fence in bottomland hardwoods. Temperature at collection was 6° C. New county record that extends the range of the species in Tennessee into the eastern portion of Fayette Co. (Redmond and Scott. 1996). Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology,

Austin Peay State University, Clarksville, Tennessee. 94 pp. (Hard copy and Internet versions, http://www.apsu.edu/amatlas/, the latter of which includes links to information on Tennessee herpetology having appeared since 1996).

Voucher image collection made under the authority of the Tennessee Wildlife Resources Agency; field work supported by State Wildlife Grant (SWG) funding under the authority of the U.S. Fish and Wildlife Service.

Submitted by **CHRIS HUNTER**, Tennessee Wildlife Resources Agency Region I Wildlife Diversity Biologist, 200 Lowell Thomas Drive, Jackson, Tennessee 38301, USA; e-mail: christopher.hunter@state.tn.us.

AMBYSTOMA OPACUM (Marbled Salamander). USA: ARKANSAS: LONOKE CO.: 2.2 km E. Ward (T5N, R9W, S25). 1 October 2005. Kelly E. McKenzie. Verified by Stanley E. Trauth. Arkansas State University Museum of Zoology Herpetological Collection (ASUMZ 29510). New county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville. 421 pp.).

Submitted by **MICHAEL V. PLUMMER**, Department of Biology, Box 12251, Harding University, Searcy, Arkansas 72149, USA (e-mail: plummer@harding.edu); and **DONALD F. McKENZIE,** Wildlife Management Institute, 2396 Cocklebur Road, Ward, Arkansas 72176, USA (e-mail: wmidm@ipa.net).

AMBYSTOMA TALPOIDEUM (Mole Salamander). USA: GEORGIA: CLARKE CO.: Whitehall Forest, man-made pond ca. 200 m SW of forest entrance gate (33.89471°N, 83.36306°W). 22 February 2004. Anna E. Liner. Verified by John Jensen. Georgia Museum of Natural History (GMNH 49911). New county record (Williamson and Moulis 1994. Distributions of Amphibians and Reptiles in Georgia. Spec. Publ. No. 3, Savannah Science Museum, Inc., Savannah).

Submitted by **ANNA E. LINER**, Warnell School of Forest Resources, University of Georgia, Athens, Georgia 30602-2151, USA; e-mail: linera@owl.forestry.uga.edu.

AMBYSTOMA TALPOIDEUM (Mole Salamander). USA: TENNESSEE: OBION CO.: Adult found under fallen timber near wetland adjacent to Walnut Log Road near Reelfoot Lake (36° 26.89'N, 89°20.84'W). 26 March 2005. Brad M. Glorioso, Matthew L. Niemiller, and Elizabeth L. Young. Verified by A. Floyd Scott. Color photo voucher in Austin Peay State University Herpetological Collection (APSU 18134). LAKE CO: Adult found in pitfall trap along drift fence in agricultural field adjacent to Carrington Road near Reelfoot Lake. (36°24.82'N, 89°25.60' W). 14 May 2005. Brad M. Glorioso and Elizabeth L. Young. Verified by A. Floyd Scott. Color photo voucher in Austin Peay State University Herpetological Collection (APSU 18135). First county records (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp.).

Submitted by **BRAD M. GLORIOSO** (e-mail: bmg2g@mtsu.edu)**, ELIZABETH L. YOUNG,** and **MATTHEW L. NIEMILLER**, Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee, 37132, USA.

NOTOPHTHALMUS VIRIDESCENS LOUISIANENSIS (Central Newt). USA: TENNESSEE: HARDIN CO.: White Oak Wildlife Management Area managed by the Tennessee Wildlife Resources Agency located in the Milledgeville Quad (35.350820°N, 88.254500° W, NAD 83). 26 May 2005. Brandon Wear. Austin Peay State University Museum of Zoology, APSU 18049 (color photo). Verified by A. Floyd Scott. One specimen caught during a visual encounter survey in bottomland hardwoods. Temperature at collection was 24°C. New county record that extends the range in Tennessee into the northwestern corner of Hardin Co. (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. [Hard copy and Internet versions, http://www.apsu.edu/amatlas/, the latter of which includes links to information on Tennessee herpetology having appeared since 1996]).

PLETHODON SERRATUS (Southern Red-backed Salamander). USA: ARKANSAS: PERRY CO.: 3.7 km N of Hollis. 15 October 2005. Henry W. Robison. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 29448). Verified by Stanley E. Trauth. New county record (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville).

Submitted by **HENRY W. ROBISON**, Department of Biological Sciences, Southern Arkansas University, Magnolia, Arkansas 71754-9354, USA; e-mail: hwrobison@saumag.edu.

SIREN INTERMEDIA (Lesser Siren). USA: ILLINOIS: CALHOUN CO.: Siren live-captured in a large-mesh fyke net in the lower unit of Swan Lake after a 24-h set (N 711657, W 4315331 using NAD27CONUS map datum in UTM's). 18 March 2005. Collected by Chad R. Dolan, John K. Tucker, and Thomas R. Timmermann, Illinois Natural History Survey (INHS 19579). Verified by Chris Phillips. First county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **CHAD R. DOLAN, JOHN K. TUCKER,** and **THOMAS T. TIMMERMANN,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA.

SIREN INTERMEDIA (Lesser Siren). USA: ILLINOIS: JERSEY CO.: Siren dip-netted in ephemeral, flood-plain pool adjacent to Long Lake (N 710947 W 4321492 using NAD27CONUS map datum in UTM's). 5 June 2003. Collected by John K. Tucker, Emily Dustman, and James T. Lamer, Illinois Natural History Survey (INHS 19341). Verified by Chris Phillips, INHS. First county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **JAMES T. LAMER, JOHN K. TUCKER,** and **EMILY DUSTMAN**, Illinois Natural History Survey, 8450

Montclair Ave, Brighton, Illinois 62012, USA.

ANURA

BARBOURULA BUSUANGENSIS (Philippine Discoglossid Frog). PHILIPPINES: PALAWAN PROVINCE: Quezon; Barangay; Panitian; Isapa Creek. 09 December 2004. Pierre Fidenci. California Academy of Sciences Photo Voucher (CAS-HPV 38). Verified by Michelle Koo. First record for Quezon Province and a ca. 80 km range extension SW from the closest known record (Alcala and Brown 1998. Philippine Amphibians. An. Illustrated Fieldguide. Bookmark, Inc., Makati City. xii + 116 pp.). Two adults were observed at night in a shaded primary forest creek (4 m wide and 0.1– 0.5 m deep) with a mixture of sand, silt, gravel, and boulder as substrate.

Submitted by **PIERRE FIDENCI,** Garcia and Associates, 1 Saunders Ave, San Anselmo, California 94960, USA; e-mail: pfidenci@garciaandassociates.com.

BOKERMANNOHYLA NANUZAE (Nanuzae's Treefrog). BRAZIL: MINAS GERAIS: Municipalidade de Ouro Preto, Serra da Brígida (20°22'S. 43°29'W, 1375 m elev.). September 2005. A. C. C. Lourenço, B. de Assis, D. P. B. da Costa, L. O. Drummond, and T. L. Pezzuti. Laboratório de Zoologia dos Vertebrados, Universidade Federal de Ouro Preto, Ouro Preto, Minas Gerais, Brazil (LZV 441A–445A). Verified by R. N. Feio. Previously known only from the mountains of Serra do Cipó (19°22'S. 43°34'W, 1200 m elev.), Municipalidade of Jaboticatubas, Minas Gerais (Bokermann and Sazima 1973. Rev. Bras. Zool. 33[3]:329–336). This record extends known distribution ca. 120 km SE from the Serra do Cipó.

Submitted by **ANA CAROLINA CALIJORNE LOURENÇO** (e-mail: carolcalijorne@gmail.com), **BRENO DE ASSIS, DÉLIO BAÊTA, LEANDRO DE OLIVEIRA DRUMMOND, TIAGO LEITE PEZZUTI,** and **MARIA RITA SILVÉRIO PIRES**, Laboratório de Zoologia dos Vertebrados, Universidade Federal de Ouro Preto, 35400-000, Ouro Preto, MG, Brazil.

BUFO ALVARIUS (Sonoran Desert Toad). MÉXICO: CHIHUAHUA: Municipality of Janos: Ejido San Pedro (30°51'30"N; 108°23'18"W), 1420 m elev. 21 August 2005. Museo de Zoología, Facultad de Ciencias, Universidad Nacional Autonoma de México photographic collection (MZFC 1372). Rancho El Uno (30°51'42"N, 10°27'36"W), 1400 m elev. 23 August 2005. MZFC 1373. Both frogs photographed by E. Ponce Guevara. Both frogs verified by Luis Canseco Márquez. First Chihuahua records from east of the Sierra Madre Occidental (Lemos-Espinal et al. 2004. Introducción a los Anfibios y Reptiles de Chihuahua. UNAM-CONABIO. 128 pp.) and an 85 km range extension NE from the lowlands of northeastern Sonora (Fouquette 1970. Cat. Amer. Amphib. Rept. 93:1–4; Frost 2005. Amphibian Species of the World. http://research.amnh.org/herpetology/amphibia/index.php). The closest records in the USA are from the Animas Valley of southwestern New Mexico (Degenhardt et al. 1996. The Amphibians and Reptiles of New Mexico. Univ. New Mexico Press. 431 pp.). Both specimens were found in natural arid grasslands.

Submitted by **GEORGINA SANTOS-BARRERA**, Museo de Zoología, Facultad de Ciencias, UNAM, A. P. 70-399, C.P. 04510, México D.F. (e-mail: gsantos@miranda.ecologia.unam.mx); **JUAN CRUZADO**, **EDUARDO PONCE GUEVARA**, **RODRIGO SIERRA CORONA,** and **JESÚS PACHECO**, Instituto de Ecología, UNAM, A.P. 70-245, C.P. 04510, México D.F.

BUFO AMERICANUS AMERICANUS (Eastern American Toad). USA: TENNESSEE: RUTHERFORD Co.: Flat Rock Cedar Glades and Barrens State Natural Area (35°51'12"N, 86°18'13"W). 29 March 2005. Brad M. Glorioso. Verified by A. Floyd Scott. Photo voucher in Austin Peay State University Herpetological Collection (APSU 18137). One adult found underneath limestone rock at edge of cedar glade. Additional specimen collected on Tassey Rd N of Readyville (35°51'52"N, 86°10'45"W). 14 November 2005. Brad M. Glorioso and Matthew L. Niemiller. Verified by Brian T. Miller. Voucher specimen in Herpetology Collection at Middle Tennessee State University (MTSU 149A). First county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp.).

Submitted by **BRAD M. GLORIOSO** (e-mail: bmg2g@mtsu.eduand) **MATTHEW L. NIEMILLER**, Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA.

BUFO CRUCIFER (NCN). BRAZIL: RIO DE JANEIRO: Municipalidade de Teresópolis: Parque Nacional de Serra dos Órgãos (PARNA-SO) (22°27'22" S, 42°59'18" W). 21 August 2005. A. M. P. T. de Carvalho-e-Silva et al. Verified by S. P. de Carvalho-e-Silva. Herpetological Collection of the Departamento de Ciências Naturais of Universidade Federal do Estado do Rio de Janeiro, Rio de Janeiro (2202-UNIRIO). The species was known from the state of Ceará to southern Espírito Santo and the northeastern state of Minas Gerais (Baldissera-Jr. et al. 2004 Arquivos do Museu Nacional 62[3]:255–282). This first state record extends the known distribution ca. 305 km southwest from Cachoeiro de Itapemirim, State of Espírito Santo (Baldissera-Jr. et al., *op. cit.*).

Submitted by **RAFAEL A. MARQUES**, Departamento de Ciências Naturais, Universidade Federal do Estado do Rio de Janeiro (UNIRIO), CEP 20290-240, Urca, Rio de Janeiro, Brazil (e-mail: marquesrafael@yahoo.com); **BRUNO B. ANNUNZIATA**, Departamento de Zoologia, Universidade Federal do Rio de Janeiro (UFRJ), C.P. 68.044, CEP 21944-970, Cidade Universitária, Rio de Janeiro, Brazil (e-mail: barcellos_ba@biologia.ufrj.br); and **ANA M. P. T. DE CARVALHO-E-SILVA**, Departamento de Ciências Naturais, Universidade Federal do Estado do Rio de Janeiro (UNIRIO), CEP 20290-240, Urca, Rio de Janeiro, Brazil (e-mail: atelles@unirio.br).

BUFO EMPUSUS (SAPO DE CONCHA). CUBA: SANCTI SPIRITUS: TOPES DE COLLANTES: Sierra Escambray, El Chorrito (21°54'5.1"N, 80°0'44.0"W), ca. 720 m elev. 1976. P. Hernández. Instituto de Ecología y Sistemática, Colección Zoológica de la Academia de Ciencias de Cuba (CZACC[I] 11678). Verified by L. V. Moreno. First record for Sierra del Escambray, where it was previously considered absent (Hedges 1999. *In* W. E. Duellman [ed.], Patterns of Distribution of Amphibians, A Global Perspective, pp. 211–254. Johns Hopkins Univ. Press, Baltimore) and the highest elevation recorded for this species, which has a wide dis-

tribution elsewhere in the lowlands of Cuba and on Isla de la Juventud and keys of the Sabana-Camagüey archipelago (Estrada and Ruibal 1999. *In* B. I. Crother [ed.], Caribbean Amphibians and Reptiles, pp. 31–62. Academic Press, San Diego).

Submitted by **ROBERTO ALONSO** (e-mail: ralonso@ecologia.cu) and **ARIEL RODRÍGUEZ**, Instituto de Ecología y Sistemática, Carr. de Varona, Km 3½, Capdevila, Boyeros, AP 8029, CP 10800, Ciudad de la Habana, Cuba.

BUFO FOWLERI (Fowler's Toad). USA: ARKANSAS: VAN BUREN Co.: Forest Road 1331A, Brock Creek Campground (N35.48929, W92.80676). 15 October 2005. Mauricio Solis et al. Voucher specimen in Arkansas State University Museum of Zoology (ASUMZ 29444). Verified by Stanley E. Trauth. First county record (Trauth et al., 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville, 421 pp.).

Submitted by **MAURICIO SOLIS**, **JOSH ENGELBERT**, **MELISSA PATRICK**, **JONATHAN STANLEY**, Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467-0599, USA (e-mail: mauricio.solis@smail.astate.edu); and **ERIKA SHELBY**, Arkansas Department of Environmental Quality, 8001 National Dr., Little Rock, Arkansas 72219, USA (e-mail: shelby@adeq.state.ar.us).

BUFO FOWLERI (Fowler's Toad). USA: NEW YORK: CHAUTAUQUA Co.: Town of Hanover, Sunset Bay on the S bank of Cattaraugus Creek at its confluence with Lake Erie. 10 June 2000. Jay DeCarolis. Verified by Alvin R. Breisch. New York State Museum (NYSM 3446). New county record (Wright and Wright 1949. Handbook of Frogs and Toads of the United States and Canada. Third ed. Comstock Publishing Associates, Ithaca. xxiv + 640 pp.). This specimen was videotaped before collection while it gave the typical advertisement call of *Bufo fowleri*. Arthur Clark of the Buffalo Museum of Science indicates a possible previous record of this species in Chautauqua Co, SW of Dunkirk on May 1960. The specimen was reportedly collected by Willard Stanley and was assigned Buffalo Museum of Science Cat. No. (A157). This specimen is now missing and could not be verified.

Submitted by **KENNETH J. ROBLEE**, New York State Department of Environmental Conservation, 270 Michigan Avenue, Buffalo, New York 14203-2999, USA.

BUFO FOWLERI (Fowler's Toad). USA: NEW YORK: ERIE Co.: Town of Evans, 80 m E of Lake Erie, 50 m N of Went Road, near Little Sister Creek. 24 August 1999. Malachy McKenna. Verified by Alvin R. Breisch. New York State Museum (NYSM 3445). New county record (Wright and Wright 1949, Handbook of Frogs and Toads of the United States and Canada. Third ed. Comstock Publishing Associates, Ithaca. xxiv + 640 pp.).

Submitted by **MALACHY MCKENNA** and **KENNETH J. ROBLEE**, New York State Department of Environmental Conservation, 270 Michigan Avenue, Buffalo, New York 14203-2999, USA.

BUFO OCELLATUS (NCN). BRAZIL: MATO GROSSO DO SUL: Município de Corguinho, Serra de Maracaju, 7 km NE of Taboco district (19°47'03.04"S, 55°15'27.61"W, elev. 272 m; WGS 84). 20 August 2005. P. Landgref Filho and R. W. Ávila. Coleção de Vertebrados da Universidade Federal de Mato Grosso do Sul, Campo Grande, Mato Grosso do Sul, Brazil (ZUFMS 793). Verified by C. Strussmann and D. H. Morais. Previously known from Pará, Mato Grosso, Minas Gerais, and Tocantins states. First state and southernmost record extends the known distribution ca. 1350 km SW from Posto Pimentel Barbosa, Mato Grosso State (Frost 2004. Amphibian Species of the World: An Online Reference. Version 3.0. 10 September 2005. http://research.amnh.org/herpetology/amphibia/ index.html).

Submitted by **ROBSON W. ÁVILA**, Departamento de Ciências do Ambiente, Campus de Corumbá, UFMS, Avenida Rio Branco, Caixa Postal 252, CEP 79301-970, Corumbá, Mato Grosso do Sul, Brazil (e-mail: robsonavila@gmail.com); and **PAULO LANDGREF FILHO**, Rua Francisco Alves Castelo, 316, ap. 16. Vila Ipiranga, CEP 79080-770, Campo Grande, Mato Grosso do Sul, Brazil (e-mail: paulograf@yahoo.com.br).

CYCLORAMPHUS CARVALHOI. BRAZIL: SÃO PAULO: Municipality of Campos do Jordão (22°42'23.2"S; 45°28'18.7"W), 1750 m elev. 20 October 2005. I. A. Martins, P. H. Bernardo, A. P. Suarez, and F. B. R. Gomes. Célio F. B. Haddad collection, deposited in Departamento de Zoologia, Universidade Estadual Paulista, Rio Claro, SP, Brasil (CFBH 9894, adult male SVL: 52.63 mm). Verified by C. F. B. Haddad. Species previously known only from the type locality (Brejo da Lapa, alto do Itatiaia, Rio de Janeiro, RJ; Heyer 1983. Arq. Zool. 30[4]:235–339. Frost 2004. Amphibian Species of the World: An Online Reference V3.0, http://research.amnh.org/herpetology/amphibia/index.html). First state record, extends known distribution ca. 200 km SW from the type locality.

Submitted by **ITAMAR ALVES MARTINS** (e-mail: istama@uol.com.br), **FELIPE BITTIOLI R. GOMES**, Universidade de Taubaté - UNITAU, Laboratório de Zoologia/IBB. 12030-1800, Taubaté, SP, Brazil; **PEDRO H. BERNARDO**, Universidade Federal de Ouro Preto (UFOP), Lab. de Zoologia dos Vertebrados, 35400-000, Ouro Preto, MG, Brazil; and **ANA PAULA SUAREZ**, Estação Ecológica de Bananal – IF, 12850-000, Bananal, SP, Brazil.

DISCOGLOSSUS PICTUS (Painted Frog). TUNISIA: GOUVERNORAT DE GABÈS: Oued el Ferd (33°46'N, 10°15'E), E of highway P-1, ca. 10.7 km E and 15 km S of Gabès. 28 March 1972. Stephen D. Busack. Verified by Robert C. Drewes. Carnegie Museum of Natural History (CM 56540). Extends the eastern range of the species along the Mediterranean coast to ca. 330 km S of Tunis, Tunisia (Schleich et al. 1996, Amphibians and Reptiles of North Africa. Koeltz Scientific Books, Koenigstein. 627 pp.). The specimen, a subadult, was taken among *Salicornia* (chenopods) at 1316 h in an area where six deep ponds house *Rana saharica*. A juvenile *Natrix maura* (CM 56543) and adult *Mesalina guttulata* (CM 56541–56542) were also found in the area.

Submitted by **STEPHEN D. BUSACK**, North Carolina State Museum of Natural Sciences, 11 West Jones Street, Raleigh, North Carolina 27601-1029, USA; e-mail: steve.busack@ncmail.net.

ELEUTHERODACTYLUS BRESSLERAE (NCN). CUBA: SANTIAGO DE CUBA: TERCER FRENTE: Sierra Maestra, vicinity of La Tabla (20°12'15.1"N; 76°23'45.2"W). 29 June 2003. R.

Alonso, A. Rodríguez, and A. Hernández. Instituto de Ecología y Sistemática, Colección Zoológica de la Academia de Ciencias de Cuba (CZACC 14.12786–97). All verified by L. V. Moreno.

First record for this species from the Sierra Maestra biogeographic region (Hedges 1999. *In* W. E. Duellman [ed.], Patterns of Distribution of Amphibians, A Global Perspective, pp. 211–254. Johns Hopkins Univ. Press, Baltimore) and ca. 220 km SW from the nearest known locality in Guantánamo Province, where the species was once thought to be endemic to the coastal area. (Schwartz 1960. Read. Publ. Mus. Art. Gall. 11:3–50).

Submitted by **ROBERTO ALONSO** (e-mail: ralonso@ecologia.cu) and **ARIEL RODRÍGUEZ**, Instituto de Ecología y Sistemática, Carr. de Varona, Km 3½, Capdevila, Boyeros, AP 8029, CP 10800, Ciudad de la Habana, Cuba.

GASTROPHRYNE CAROLINENSIS (Eastern Narrow-mouthed Toad). USA: TENNESSEE: Fayette Co.: Wolf River Wildlife Management Area managed by the Tennessee Wildlife Resources Agency located in the SE Moscow Quad (35.029000°N, 89.265350°W, NAD 83). 19 October 2004. Brandon Wear. Austin Peay State University Museum of Zoology, APSU 18053 (color photo). Verified by A. Floyd Scott. One specimen found in a drift fence in bottomland hardwoods. Temperature at collection was 21°C. New county record that extends the range of the species in Tennessee into the eastern portion of Fayette Co. (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. [Hard copy and Internet versions, http://www.apsu.edu/amatlas/, the latter of which includes links to information on Tennessee herpetology having appeared since 1996]).

Voucher image collection made under the authority of the Tennessee Wildlife Resources Agency; field work supported by State Wildlife Grant (SWG) funding under the authority of the U.S. Fish and Wildlife Service.

Submitted by **CHRIS HUNTER**, Tennessee Wildlife Resources Agency Region I Wildlife Diversity Biologist, 200 Lowell Thomas Drive, Jackson, Tennessee 38301, USA; e-mail: christopher.hunter@state.tn.us.

GASTROPHRYNE CAROLINENSIS (Eastern Narrow-mouthed Toad). USA: TENNESSEE: Grundy Co.: Abandoned rock quarry near entrance to Crystal Cave, Tennessee Cave Survey Num. GD10 (35°16' 28"N, 85°51'21"W). 12 May 2005. Matthew L. Niemiller, Jason M. Todd, Brian T. Miller, and Nathaniel G. Mann. Verified by A. Floyd Scott. Color photo voucher in Austin Peay State University Herpetological Collection (APSU 18133). Three adults found underneath limestone rock. First county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp.).

Submitted by **MATTHEW L. NIEMILLER** (e-mail: mln2a@mtsu.edu), **JASON M. TODD**, **BRIAN T. MILLER** (e-mail: bmiller@mtsu.edu), Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee, 37132, USA; and **NATHANIEL G. MANN**, 225 Apple Valley Lane, Morrison, Tennessee 37357, USA.

HYLA CINEREA (Green Treefrog). USA: INDIANA: Posey Co.: Pointe Township, ca. 15 km SW Mount Vernon (37.8229N, 88.0029W, NAD 83). 10 June 2005. Zack Walker and Nathan Engbrecht. Verified by Chris Phillips. Photo voucher in Illinois Natural History Survey (INHS2005a). New county record and second record for the state of Indiana (Lodato et al. 2004. Herpetol. Rev. 35:281. Minton 2001. Amphibians and Reptiles of Indiana. 2nd ed., revised. Indiana Acad. Sci. 404 pp.). This record extends the range northward into the southwestern section of Indiana and appears to be the result of a natural expansion in the range of this species. Adults were in chorus at an oxbow slough dominated by Bald Cypress (*Taxodium distichum*) and Buttonbush (*Cephalanthus occidentalis*) near the conjunction of the Ohio and Wabash Rivers. A second chorus was later heard from the backwaters of Hovey Lake, ca. 3.75 km ESE of the oxbow slough. The origin of these populations is currently unknown, however, nearby populations of *H. cinera* in adjacent Union and Henderson counties, Kentucky might serve as source populations for this new locality.

Submitted by **ZACHARY WALKER** (e-mail: Zwalker@dnr.IN.gov), **NATHAN ENGBRECHT** (e-mail: Nengbrecht@dnr.IN.gov), and **REBECCA SCHMITT**, Indiana Department of Natural Resources – Wildlife Diversity/Herpetology, 533 East Miller Drive, Bloomington, Indiana 47401, USA.

HYLA GRATIOSA (Barking Treefrog). USA: TENNESSEE: Hardin Co.: White Oak Wildlife Management Area managed by the Tennessee Wildlife Resources Agency. Milledgeville Quad (35.340010°N, -88.333540°W, NAD 83). 7 July 2005. Brandon Wear. Austin Peay State University Museum of Zoology, APSU 18052 (color photo). Verified by A. Floyd Scott. One specimen caught in a funnel trap along a drift fence in bottomland hardwoods. Temperature at collection was 25°C. New county record that extends the range in Tennessee into the northwestern corner of Hardin Co. (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. [Hard copy and Internet versions, http://www.apsu.edu/amatlas/, the latter of which includes links to information on Tennessee herpetology having appeared since 1996]).

Voucher image made under the authority of the Tennessee Wildlife Resources Agency; field work supported by State Wildlife Grant (SWG) funding under the authority of the U.S. Fish and Wildlife Service.

RANA BEDRIAGAE (Bedriaga's Frog). MALTA: GOZO ISLAND: L-Ghadira ta' Sarraflu (36°02'3"N; 14°12'2"E). 500 m elev. 5 September 2004. Jonathan Abela, Nimrod Mifsud, Esther Schembri, Arnold Sciberras, and Jeffery Sciberras. National Museum of Natural History, Mdina, Malta (NMNHM AN01105). Verified by Ulrich Sinsch, Universität Bonn (on the basis of color photographs and recordings of advertisement calls). Introduced to the Maltese Islands, where *Discoglossus pictus pictus* is the only native amphibian (Baldacchino and Schembri 2002. Amfibji, Rettili, u Mammiferi fil-gzejjer Maltin. Il-Pjeta, Pubblikazzjonijiet Indipendenza, xii + 256 pp., Malta; Lanza 1972. Lav. Soc. Ital. Biogeogr. N. Ser., 3:755–804). Calls were first heard from the permanent freshwater pool at Ta' Sarraflu in April 2000, when approximately six individuals were calling. Individuals were first seen on 27 May 2004. Since then, choruses of at least 50 frogs have been heard around the pool. Eggs, tadpoles, and froglets were seen there, indicating successful reproduction. Choruses are now heard at two other localities on Gozo Island, indicating that the species is spreading.

RANA BERLANDIERI (Rio Grande Leopard Frog). MEXICO: SONORA: 13 km SW San Luis Río Colorado, 30 m E Hwy 40 (32°24'34.1"N, 114°52'52.5"W), 27 m elev. 9 April 2005. James C. Rorabaugh and Jeffrey M. Servoss. Verified by T. Brennan. Arizona State University voucher photographs (ASU HP-00020–21). First records from Sonora; the closest accounts are from adjacent portions of Baja California Norte, Mexico and Arizona, USA (Grismer 2002. Amphibians and Reptiles of Baja California: Including Its Pacific Islands and the Islands in the Sea of Cortez. Univ. of California Press, Berkeley. 399 pp.; Rorabaugh et al. 2002. Southwest. Nat. 47:12–20). This Sonoran population most likely originated by means of invaders from southwestern Arizona (Platz et al. 1990. Copeia 1990:324–333), using the Río Colorado or agricultural canals as dispersal routes. Both specimens were observed in a concrete-lined ditch in an agricultural area within the valley of the Río Colorado.

Submitted by **JAMES C. RORABAUGH** (e-mail: Jim_Rorabaugh@fws.gov) and **JEFFREY M. SERVOSS**, U.S. Fish and Wildlife Service, 2321 West Royal Palm Road, Suite 103, Phoenix, Arizona 85021, USA.

RANA CASCADAE (Cascades Frog). USA: WASHINGTON: JEFFERSON CO.: 47°47.56'N, 124°23.80'W, 98 m elev. 17 March 2005. R. O'Donnell and J. MacCracken. Voucher photographs in the University of Washington Burke Museum (UWBM 2131–2133). Verified by Marc P. Hayes. Thirteen egg masses were found in a ca. 2–3 m 15 cm deep puddle with a mud/silt substrate at the junction of two logging roads. Embryos ranged from stage 14 to 24, including two egg masses that had begun to hatch (Gosner 1960. Herpetologica 16:183–190). A brief search of the surrounding area did not reveal any adults. JEFFERSON Co: N47°50.68', W124°22.87', 109 m elev. 3 May 2005. R. O'Donnell, L. Beatty, and R. McGinnis. Voucher photograph in the University of Washington Burke Museum (UWBM 2134). Verified by Marc P. Hayes. One juvenile found near a stream at a washed-out crossing of a decommissioned logging road. *Rana cascadae* is generally considered a species of high elevations. These observations represent new published low elevation records for the species by over 120 m (Stebbins 2003. Western Reptiles and Amphibians, 3rd ed. Houghton Mifflin Company, Boston, 533 pp.). However, several museum specimens are available from low elevations on the western side of the Olympic Peninsula which have not been reported in the literature from 167 m (MVZ 65571), ca. 100 m (PSM 1458), and ca. 73 m (CAS 47708–47723). The new records reported here provide needed recent confirmation of low-elevation records from the Olympic Peninsula which have not been reported since the 1910s, where the species had been thought to be extirpated (Leonard et al. 1993. Amphibians of Washington and Oregon. Seattle Audubon Society, Seattle, 168 pp.; McAllister 1995. Northwest Fauna 3:81–112).

SCAPHIOPUS COUCHII (Couch's Spadefoot). USA: COLORADO: Las Animas Co.: Live on Colorado Highway 109 during cold rain (4.25 km W, 0.25 km N Lone Mesa; NAD27, UTM Zone 13, Easting 646887, Northing 4164548). 10 June 2005. L. J. Livo. Photographic print assigned UCM Ancillary Collection #155. Verified by H. M. Smith. First record for county and southernmost record in Colorado, further expanding the known range in the state (Hammerson 1999. Amphibians and Reptiles in Colorado, 2nd Ed. University Press of Colorado, Niwot, Colorado).

Submitted by **LAUREN J. LIVO**, Department of Integrative Physiology, University of Colorado, Boulder, Colorado 80309-0354, USA.

SCINAX BERTHAE (Dwarf-snouted Treefrog). ARGENTINA: BUENOS AIRES: Partido de Magdalena: Atalaya's Beach, 500 m W of Río de La Plata shore line (35°01'54"S, 57°29'59"W). 8 February 2000. R. Cajade, L. Alcalde, and G. S. Natale. Museo de La Plata, Buenos Aires, Argentina (MLP 1817–1820, four adult males). Partido de Punta Indio: Punta Indio's Beach, 200 m W of Río de La Plata shore line (35°16'37"S, 57°13'03"W). 27 December 2002. L. Alcalde, G. S. Natale, and D. P. Ferraro. Museo de La Plata, Buenos Aires, Argentina (MLP 3491–3492, 3497–3498, four adult males). Verified by Nestor G. Basso. *Scinax berthae* was recorded for southern Paraguay, Uruguay, southern Brazil, and northeastern Argentina (Braun and Braun 1975. Iheringia zool. 46:19 – 24; Kehr 1983. Neotropica 29[81]:43–44; Langone and Prigioni 1988. Bol. Soc. Zool. Uruguay (2 da época) 4:1–4; Lopez et al. 1999. Cuad. Herpetol. 13[1–2]:105–106; Waller and Beccaceci 2000. Cuad. Herpetol. 14[1]:75). The southernmost known locality is the type locality: Punta Lara, Buenos Aires province, Argentina (Barrio 1964. Copeia 1964[3]:583–585). However, Straneck et al. (1993. Catálogo de Voces de Anfibios Argentinos. Tomo I. L.O.L.A.:1–130) shows a map indicating that the southernmost locality of *Scinax berthae* is Bahia de Sanborombón, ca. 150 km airline S from Punta Lara, but there are no vouchers supporting this location. These records represent the southernmost locations for *Scinax berthae* supported by voucher specimens and extend the range of the species ca. 100 km airline S from Punta Lara.

GYMNOPHIONA

CAECILIA GRACILIS. BRAZIL: MARANHÃO: Urbano Santos Municipality (ca. 40 m elev.): Fazenda Santo Amaro (3°12'28"S, 43°24'12"W) 6 and 12 March 2004. J. A. M. dos Santos. Museu de Zoologia da Universidade Federal da Bahia, Salvador, Bahia (MZUFBA 6010–6014 captured by digging in soil in a gallery forest). Verified by M. S. Hoogmoed. The previously known distribution was restricted to Surinam, French Guiana, northeastern Peru, and Pará state in the northern region of Brazil (Nussbaum and Hoogmoed 1979. Zoologische Mededelingen 54[14]:217–235). This new state record, extends range ca. 550 km eastward from Acará in Pará state. The occurrence of *Caecilia gracilis* in a gallery forest in Urbano Santos expands the distribution of this species to the Cerrado domain.

TESTUDINES

APALONE SPINIFERA (Spiny Softshell). USA: ILLINOIS: Pike Co.: found on bank of the Mississippi River in Pool 22 at approximate river mile 316 (39.49199°N and 091.06004°W, NAD83 map datum). 22 September 2004. James T. Lamer. INHS 19662. Verified by Chris Phillips, INHS. Turtle found dead of unknown causes on bank. Specimen is first county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **JAMES T. LAMER** and **JOHN K. TUCKER,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA.

APALONE SPINIFERA (Spiny Softshell). USA: ILLINOIS: Sangamon Co.: Softshell was live-trapped in Lake Springfield using a baited Legler-style hoop trap baited with fish carcasses. N 0270173 and W 4398154 using NAD27 CONUS map datum in UTM's. 21 August 2005. Specimen collected by Chad R. Dolan and James T. Lamer. Turtle is a large female: carapace length = 468 mm, carapace width = 346 mm, carapace height = 108 mm, plastron length = 322 mm, and mass = 8700 g. Turtle was photographed by James T. Lamer and John K. Tucker and then released back into Lake Springfield. INHS Herpetological Photograph 2005.23. Verified by Chris Phillips, Illinois Natural History Survey. First county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **JAMES T. LAMER, CHAD R. DOLAN,** and **JOHN K. TUCKER,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA.

CHELYDRA SERPENTINA (Snapping Turtle). USA: ILLINOIS: Christian Co.: Snapping turtle was live-trapped off of 1400 E Rd on Lake Taylorville using a baited Legler-style hoop trap. N 0305352 and W 4372318 using NAD27 CONUS map datum in UTM's. 20 August 2005. Specimen collected by James T. Lamer and Chad R. Dolan. INHS 19660. Verified by Chris Phillips, Illinois Natural History Survey. Specimen is a first county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **JAMES T. LAMER, CHAD R. DOLAN,** and **JOHN K. TUCKER,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA.

CHELYDRA SERPENTINA (Snapping Turtle). USA: ILLINOIS: Montgomery Co.: Snapping turtle was live-trapped in a cove of Lake Lou Yaeger using a baited Legler-style hoop trap baited with fish carcasses. GPS coordinates are as follows: N 0271409 and W 4339665 using NAD27 CONUS map datum in UTM's. 21 August 2005. Specimen collected by Chad R. Dolan and James T. Lamer. INHS 19659. Verified by Chris Phillips, Illinois Natural History Survey. Specimen is a first county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **JAMES T. LAMER, CHAD R. DOLAN,** and **JOHN K. TUCKER,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA.

CHELYDRA SERPENTINA (Snapping Turtle). USA: TEXAS: Jack Co.: (33.409°N, 98.197°W, 278 m elev.), DOR on St. Route 59. 17 June 2005. Jesse M. Meik and A. Michelle Lawing. Verified by Carl J. Franklin. University of Texas at Arlington Collection of Vertebrates (UTA R-53461). First county record (Dixon 2000. Amphibians and Reptiles of Texas. 2nd Edition. Texas A&M Univ. Press, College Station).

Submitted by **JESSE M. MEIK** and **A. MICHELLE LAWING**, Department of Biology, The University of Texas at Arlington, Arlington, Texas 76012, USA; e-mail: jmeik@uta.edu.

CHRYSEMYS PICTA (Painted Turtle). USA: ILLINOIS: Christian Co.. Turtle was live-trapped off of 1400 E Rd on Lake Taylorville between 800 N and 900 N Rd using a baited Legler-

style hoop trap. N 0305332 and W 4372345 using NAD27 CONUS map datum in UTM's. 20 August 2005. Specimen collected by James T. Lamer and Chad R. Dolan. INHS 19661. Verified by Chris Phillips, Illinois Natural History Survey. First county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **CHAD R. DOLAN, JAMES T. LAMER,** and **JOHN K. TUCKER,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA.

GRAPTEMYS OUACHITENSIS (Ouachita Map Turtle). USA: MISSOURI: Marion Co.. Turtle was caught alive via dip net after being stunned while electrofishing off of the bank of the Mississippi River at approximate river mile 323. 39.87130°N, 091.45054°W (NAD83). 30 August 2005. Collected by Chad R. Dolan and James T. Lamer. UMC 848P. Verified by Richard Daniel, Universtiy of Missouri-Columbia and Jeff Briggler, Missouri Department of Conservation. First county record (Johnson 2000. The Amphibians and Reptiles of Missouri, 2nd ed. Missouri Dept. of Conservation, Jefferson City). The turtle collected was male: carapace length = 96 mm, carapace width = 76 mm, carapace height = 33 mm, plastron length = 80 mm, and mass = 110 g.

Submitted by **CHAD R. DOLAN, JAMES T. LAMER, JOHN K. TUCKER,** and **ERIC J. GITTINGER,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA.

LEPIDOCHELYS OLIVACEA (Olive Ridley Seaturtle). Western North Atlantic Ocean: (43°11.0'N, 53°53.1'W). 22 October 2003. National Marine Fisheries Pelagic Longline Observer, David Sheuerman. Verified by Peter Dutton of the NMFS Marine Turtle Molecular Ecology Laboratory using mtDNA control region sequencing (Dutton et al. 1999. J. Zool., London 248:397–409). Biopsy tissue sample deposited at the National Marine Fisheries Service / Southwest Fisheries Science Center's Marine Turtle Molecular Ecology Laboratory, La Jolla, California (Reference ID: Z35983), and photographs deposited at the University of Florida (UF 145103). This is the northernmost record of this species in the western North Atlantic. *L. olivacea* is rare in the western North Atlantic outside the tropics. It was previously reported in waters surrounding southern Florida (Foley et al. 2003. Marine Turtle Newsl. 101:23–25), the Caribbean (Carr et al. 1982. Surveys of Sea Turtle Populations and Habitats in the western Atlantic. NOAA Tech. Memo. NMFS-SEFSC-91: 98 pp.), and more commonly along the northern coast of South America (Marcovaldi 2001. *In* Eckert and Abreu Grobois [eds.], Proceedings of the Regional Meeting: Marine Turtle Conservation in the Wider Caribbean Region: a Dialogue for Effective Regional Management. Santo Domingo, Dominican Republic, 16–18 November 1999, pp. 52–56. WIDECAST, IUCN-MTSG, WWF, and UNEP-CEP). This subadult Olive Ridley was incidentally captured during a pelagic longline fishery interaction. It measured 53.3 cm standard straight carapace length, and had inframarginal pores and 6 left and 7 right costal scutes. The specimen was released alive back into the wild (US federally-listed species) after the 9/0 J-hook was removed from its mouth.

Submitted by **LESLEY W. STOKES**, Cooperative Institute of Marine and Atmospheric Sciences, a Joint Institute of the University of Miami and NOAA Fisheries, Southeast Fisheries Science Center, 75 Virginia Beach Drive, Miami, Florida 33149, USA (e-mail: Lesley.Stokes@noaa.gov); and **SHERYAN P. EPPERLY**, National Marine Fisheries Service, Southeast Fisheries Science Center, 75 Virginia Beach Drive, Miami, Florida 33149, USA (e-mail: Sheryan.Epperly@noaa.gov).

TERRAPENE CAROLINA TRIUNGUIS (Three-toed Box Turtle). USA: ARKANSAS: Cleveland Co.: 4.8 km N of Rison, Arkansas on U.S. Hwy. 79 (Sec. 23, T8S, R10W). 13 November 2005. H. W. Robison. Arkansas State University Museum of Zoology, Herpetological Collection photograph (ASUMZ 29518). Verified by Stanley E.Trauth. New county record in southwestern Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville, 421 pp.).

Submitted by **HENRY W. ROBISON**, Department of Biological Sciences, Southern Arkansas University, Magnolia, Arkansas 71754-9354, USA; e-mail: hwrobison@saumag.edu.

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). USA: ILLINOIS: Christian Co.. Turtle was live-trapped off of 1400 E Rd on Lake Taylorville between 800 N and 900 N Rd using a baited Legler-style hoop trap. N 0305332 and W 4372345 using NAD27 CONUS map datum in UTM's. 20 August 2005. Specimen collected by James T. Lamer and Chad R. Dolan. INHS 19663. Verified by Chris Phillips, Illinois Natural History Survey. Specimen is a first county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **CHAD R. DOLAN, JAMES T. LAMER,** and **JOHN K. TUCKER,** Illinois Natural History Survey, 8450 Montclair Ave, Brighton, Illinois 62012, USA.

LACERTILIA

ANOLIS PUNCTATUS (Lagartixa Verde da Amazônia; Amazon Green Anole). BRAZIL: MINAS GERAIS: Municipalidade de Caratinga: Reserva Particular do Patrimônio Natural Feliciano Miguel Abdala (19°43'53"S, 41°49'00"W). 03 August 2000. J. Cassimiro. Museu de Zoologia da Universidade de São Paulo, São Paulo, Brazil (MZUSP 95077). Verified by M. T. Rodrigues. Formerly recognized as an Amazonian species, occurring probably in French Guiana and Suriname, parts of Guyana, Venezuela (questionable), Colombia, Ecuador, Peru, Bolivia, and Brazil (Peters and Donoso-Barros 1970. Bull. U.S. Natl. Mus. 297:1–293). In Brazil the species is found in most of Amazonia (Amapá, Maranhão, Pará, Amazonas, Rondônia, Acre; doubtfully Roraima), and in the Atlantic Forest (Avila-Pires 1995. Zool. Verh. Leiden 299:1–706). In the Atlantic Forest, the southernmost limit is Beach of Boracéia, state of São Paulo (Vanzolini 1972. Pap. Avulsos Zool., S. Paulo 26:83–115). However, there are few literature records giving accurate Brazilian localities. This first state record extends the known distribution ca. 185 km airline W from the closest known locality in Linhares, state of Espírito Santo (Rocha 1998. Anais do VIII Seminário Regional de Ecologia:869–881).

Submitted by **JOSÉ CASSIMIRO,** Departamento de Zoologia, Instituto de Biociências, Universidade de São Paulo, Caixa Postal 11.461, CEP 05422-970, São Paulo, SP, Brazil (e-mail: geckoides@yahoo.com.br); **VINÍCIUS XAVIER,** Universidade

Federal de Alfenas, Rua Gabriel Monteiro da Silva, 714, CEP 37130-000, Alfenas, MG, Brazil (e-mail: vinic@int.efoa.br); and **JAIME BERTOLUCI,** Departamento de Ciências Biológicas, Escola Superior de Agricultura "Luiz de Queiroz," Universidade de São Paulo, Av. BACHIA HETEROPA LINEATA (Worm Lizard). VENEZUELA: TRUJILLO: Municipio Pampanito, Urbanización "El Prado" (9°25'N, 70°27'W), 480 m elev. 20 November 2002. C. Cuevas. Museo de Biología de La Universidad del Zulia, Maracaibo (MBLUZ-R-0763). ZULIA: Municipio Jesús María Semprún, Casigua-El Cubo (8°45'N, 72°30'W). 12 August 1965. R. Hernández. Museo de Historia Natural La Salle, Caracas (MHNS-2497). Both verified by Gilson Rivas Fuenmayor. The distribution of this subspecies is restricted to Venezuela (Dixon 1973. Univ. Kansas Mus. Nat. Hist., Misc. Publ. 57:1–47). Previously known from the Capital District, Falcón, Yaracuy, and Portuguesa states (Dixon, *op. cit.*; Donoso-Barros 1968. Carib. J. Sci. 8[3–4]:105–122; Esqueda et al. 2001. Herpetol. Rev. 32:198–200; Markezich 2002. Herpetol. Rev. 33:69–74; Mijares and Arends 1999. Herpetol. Rev. 30:115). The specimens reported herein are the first records for these two states and establish the species in the Maracaibo Lake Basin. One specimen (MHNS-2497) extends the distribution ca. 210 km W (airline) from the nearest locality account (Markezich, *op. cit.*).

Submitted by **FERNANDO J. M. ROJAS-RUNJAIC**, Museo de Historia Natural La Salle, Sección de Herpetología, Apartado Postal 1930, Caracas 1010-A, Venezuela (e-mail: fernando.rojas@fundacionlasalle.org.ve); and **EDWIN E. INFANTE RIVERO,** La Universidad del Zulia, Facultad Experimental de Ciencias, Museo de Biología de La Universidad del Zulia, Sección de Herpetología, Apartado Postal 526, Maracaibo 4011, Venezuela (e-mail: edwinfantembluz@hotmail.com).

COLEODACTYLUS SEPTENTRIONALIS (Pygmy Gecko). VENEZUELA: ANZOATEGUI: San Diego de Cabruta, ca. 50 m elev. (10°06'55"N, 64°38'18"W). December 2003. Erik Arrieta. Museo de Historia Natural La Salle, Caracas (MHNLS 17084). Verified by César L. Barrio-Amorós. This tiny gecko has been previously reported from the northern part of Roraima (Brazil), western Suriname, the Pacaraima foothills (Guyana), and the Venezuelan Guiana. In this last country it is known from a few localities in the states of Delta Amacuro, Bolívar, and Monagas. First state record and the northwesternmost locality known, extending the distribution 273 km NW of the nearest locality in the Morichal del Río Uracoa, Monagas state (Ávila-Pires 1995. Zool. Verhand., Leiden 299:1–706; Rivas and Molina 2001. Herpetol. Rev. 32:275).

Submitted by **GILSON A. RIVAS F.** (e-mail: gilson.rivas@fundacionlasalle.org.ve), and **FERNANDO J. M. ROJAS-RUNJAIC,** Museo de Historia Natural La Salle, Sección de Herpetología, Apartado Postal 1930, Caracas 1010-A, Venezuela (e-mail: fernando.rojas@fundacionlasalle.org.ve).

EUMECES TETRAGRAMMUS BREVILINEATUS (Short-lined Skink). USA: TEXAS: STERLING CO.: 16.1 km E Sterling City off St. Hwy. 163. 8 April 2001. J. A. Holm and K. Perez. Angelo State University Natural History Collection (ASNHC 13555). Verified by J. K. McCoy. New county record partially filling a distributional gap among Coke, Irion, and Tom Green counties (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station, Texas. 421 pp.).

Submitted by **CHRIS T. McALLISTER**, Department of Biology, Angelo State University, San Angelo, Texas 76909, USA (e-mail: chris.mcallister@angelo.edu); and **JAMES A. HOLM**, 201 S. Heights Blvd., Apt 2913, Houston, Texas 77007, USA (e-mail: jaz_holm@hotmail.com).

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). USA: NEVADA: CLARK CO.: Mesquite (36°48'49"N, 114°04'02"W). 26 May 2005. On grounds of Virgin River Casino on the north side of Interstate 15. Three individuals deposited at Arizona State University Museum (ASU 35720–35722). Verified by A. T. Holycross. Previously known in Nevada only from Las Vegas (Saethre and Medica 1993. Herpetol. Rev. 24:154–155; A. Heindl [UNLV Museum], pers. comm.). These specimens extend the range in Nevada ca. 130 km to the NE. *H. turcicus* appears to be spreading in human-occupied area along the Interstate 15 corridor via purposeful or accidental releases.

Submitted by **ROBERT N. REED, LESTER J. TRENKAMP, BROOK E. COX**, and **SELENA M. SORENSEN,** Department of Biology, Southern Utah University, Cedar City, Utah 84720, USA; e-mail: reed@suu.edu.

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). USA: UTAH: WASHINGTON CO.: St. George. 8 October 2005. Gecko was found in the Dixie Downs region of city of St. George, in a suburban backyard. One specimen deposited at Monte L. Bean Museum, Brigham Young University (BYU 5096). Verified by J. Sites. New state record. This specimen extends the range of *H. turcicus* ca. 65 km to the NE; the closest previously known population is in Mesquite, Nevada (Reed et. al. 2006. Herpetol. Rev. 37:106) *H. turcicus* appears to be spreading in human-occupied areas along the Interstate 15 corridor via purposeful or accidental releases. However, St. George and its environs are likely the northernmost limit of the species' advance along I-15, as the interstate rises to ~1800 m elevation soon after heading north from St. George.

Submitted by **ROBERT N. REED, EDWARD SNOW, LESTER J. TRENKAMP, BROOK E. COX,** and **SELENA M. SORENSEN**, Department of Biology, Southern Utah University, Cedar City, Utah 84720, USA; e-mail: reed@suu.edu.

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). USA: VIRGINIA: RICHMOND CO.: 3500 Pemberton Rd., Richmond (N 41.71074 17; W 80.3198, NAD1927), 5 August 2005. Verified by Raymond Fernald, Virginia Department of Game and Inland Fisheries. (KU-CT 958 photo voucher, University of Kansas). Populations of Mediterranean House Geckos have become established in many places in the southern United States (NatureServe 2005. NatureServe Explorer: An Online Encyclopedia of Life [web application]. Version 4.5. NatureServe, Arlington, Virginia. Available http://www.natureserve.org/explorer). Seven individuals, two neonates and five adults, were removed from a building in Richmond, Virginia. One female deposited two eggs shortly after capture. This is the northernmost reproducing population of *H. turcicus*

in the eastern United States (NatureServe, *op. cit.*) and the first such record for Virginia (Mitchell 1994. The Reptiles of Virginia. Smithsonian Inst. Press, viii + 352 pp.; Mitchell and Reay 1999. Spec. Publ. No. 1, Virginia Dept. of Game and Inland Fisheries, Richmond). This population might be able to overwinter successfully because it occupies a building that maintains suitable environmental conditions year-round.

Submitted by **JOHN D. KLEOPFER**, Virginia Department of Game and Inland Fisheries, 5806 Mooretown Rd., Williamsburg, Virginia 23188, USA (e-mail: john.kleopfer@dgif.virginia.gov); **SUSAN H. WATSON,** Virginia Department of Game and Inland Fisheries, 4010 West Broad St., Richmond, Virginia 23230, USA (e-mail: susan.watson@dgif.virginia.gov); and **JOSEPH C. MITCHELL**, Department of Biology, University of Richmond, Richmond, Virginia 23173, USA (e-mail: jmitchel@richmond.edu).

LIOLAEMUS DONOSOBARROSI. ARGENTINA: MENDOZA PROVINCE: San Rafael Departament: Surroundings of Lake El Nihuil. 15 February 1982. A. Malbec. Museo de Historia Natural de San Rafael, San Rafael, Mendoza, Argentina (MSR-H 1183: adult female, 56.11 mm SVL and MSR-H 1184: adult male, 56.64 mm SVL). Verified by F. Lobo. Previously known from Matancilla and Agua del Toro, Malargüe Department, Mendoza Province (Cei and Roig 1976. Deserta 4:69–91), and Cerro Bandera, Departamento Zapala, Neuquén Province (Avila 1996. Cuad. Herpetol. 9[2]:109–110). The present record extends the northeastern range 190 km from Agua del Toro (Cei and Roig, *op. cit.*).

Submitted by **CRISTIAN ABDALA**, Instituto de Herpetología de la Fundación Miguel Lillo, Miguel Lillo 251, 4000, Tucumán, Argentina (e-mail: popper@tucbbs.com.ar); and **RICARDO JUAREZ**, Departamento de Zoología, Museo de Historia Natural de San Rafael, Parque Mariano Moreno, 5600, San Rafael, Mendoza, Argentina (e-mail: ricardoj73@hotmail.com).

LIOLAEMUS LOBOI. ARGENTINA: NEUQUÉN: Departamento Huiliches: Vicinity of San Ignacio, San Ignacio, 39º54'S 70º51'W. 14 March 1961. L. E. Pena. Field Museum of Natural History, Chicago (FMNH 133128, 133131, 133746, 133752, 133755, 133760). Verified by S. Quinteros. Extends the range 145 km NE from the only previously known locality: Neuquén Province, Los Lagos Department, intersection between national route 237 and national route 231 (type locality, Abdala 2003. Cuad. Herpetol. 17[1–2]:3–32).

Submitted by **CRISTIAN ABDALA**, Instituto de Herpetología de la Fundación Miguel Lillo, Miguel Lillo 251, 4000, Tucumán, Argentina (e-mail: popper@tucbbs.com.ar); and **FERNANDO LOBO**, CONICET -Cátedra de Anatomía Comparada, Facultad de Ciencias Naturales, Universidad Nacional de Salta, Bolivia 5150, 4400, Salta, Argentina (e-mail: flobo@unsa.edu.ar).

LUPEROSAURUS BROWNI (Brown's Flap-legged Gecko). SINGAPORE: Pulau [= island] Tekong, Batu Koyok area (1°24'N, 104°02'E). In scrub vegetation near secondary rainforest; observed about 1 m off the ground, clinging in a horizontal position to the stem of an unidentified herbaceous climbing plant, and occurring syntopically with the house geckos *Hemidactylus frenatus* and *Gekko monarchus*. 4 August 2005 at ca. 2200 h. Kelvin K. P. Lim and Norman T-L. Lim. Raffles Museum of Biodiversity Research Zoological Reference Collection (ZRC 2.6140, adult male, SVL 58.9 mm, tail incomplete: regenerated). Verified by Indraneil Das. New country record (Lim and Lim 1992. A Guide to the Amphibians and Reptiles of Singapore, Singapore Science Centre, 160 pp.); second record for the Malay Peninsula (Brown et al. 2000. Copeia 2000:191–209; Das 2004. Lizards of Borneo, Natural History Publications [Borneo], p. 49).

Submitted by **KELVIN K. P. LIM** and **NORMAN T-L. LIM**, Department of Biological Sciences, National University of Singapore, Singapore 119260.

PSEUDOGONATODES MANESSI (Pygmy Gecko). VENEZUELA: SUCRE: trail between Macuro and Cerro Azul, Península de Paria, ca. 700 m elev. (10°41'33"N, 61°57'47"W). 19 July 2002. G. Rivas and C. L. Barrio-Amorós. Museo de Historia Natural La Salle, Caracas (MHNLS 16202). Verified by W. Schargel. *P. manessi* is an endemic species from Venezuela, known previously from two relatively close localities in the Central Coastal Range (Ávila-Pires and Hoogmoed 2000. Zool. Meded., Leiden 73[12]:209–223). First state record, extends the known distribution 526 km E from Los Canales de Naiguatá, Vargas state (Ávila-Pires and Hoogmoed, *op. cit.*).

Submitted by **GILSON A. RIVAS F.** (e-mail: gilson.rivas@fundacionlasalle.org.ve), **FERNANDO J. M. ROJAS-RUNJAIC** (e-mail: fernando.rojas@fundacionlasalle.org.ve), Museo de Historia Natural La Salle, Sección de Herpetología, Apartado Postal 1930, Caracas 1010-A, Venezuela; and **CÉSAR L. BARRIO-AMORÓS,** Fundación Andígena, Apartado 210, Mérida 5101-A, Venezuela (e-mail cesarlba@yahoo.com).

SCELOPORUS UNDULATUS CONSOBRINUS (Southern Prairie Lizard). USA: MISSOURI: Scott Co.: 6.5 km S Chaffee on State Hwy 77, 800 m E on Bluebird Lane (37°07.414'N, 89°40.259'W). 21 September 2005. Alex B. Heeb and Jacob D. Heeb. Verified by John S. Scheibe, Department of Biology, Southeast Missouri State University. Photographs deposited in Southeast Missouri State University Natural History Museum (SEMO-15105). One young animal (total length = 67.4 mm) was found on a W-facing concrete porch, surrounded by a clearing of 100 m within a hardwood deciduous forest. New county record (Daniel and Edmond 2005. Atlas of Missouri Amphibians and Reptiles. 68 pp.).

Submitted by **ALEX B. HEEB**, 159 Bluebird Lane, Chaffee, Missouri 63740, USA.

SERPENTES

AGKISTRODON CONTORTRIX (Copperhead). USA: ILLINOIS: St. Clair Co.: Sugar Loaf Township (38°27.947'N, 90°09.250'W). 29 June 2004. Robert Weck. Verified by Chris Phillips. Illinois Natural History Survey (INHS 19540). Adult found DOR on Stemler Road. New locality record and first voucher specimen for St. Clair Co. (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **ROBERT WECK**, Department of Biology, Southwestern Illinois College, 2500 Carlyle Avenue, Belleville, Illinois,

62221, USA; e-mail: bob.weck@swic.edu.

ATRACTUS LATIFRONS. BOLIVIA: DEPTO. SANTA CRUZ: GUARAYOS: Río Negrillo: 62°46'W, 15°05'S, 300 m elev. 30 October 2002. R. Montaño. Museo Historia Natural Noel Kempff Mercado, Santa Cruz de la Sierra (MNKR 3438–3439). Río NEGRO: 62°36.7'W, 14°59.5'S, 300 m elev. 28 October 2002. R. Montaño. MNKR 3436-3437. Campamento Río San Martín: 61°56'W, 15°03'S, 250 m elev. November 1992. D. Rumiz. MNKR 505. Verified by P. Passos. First country records, species previously known from Brazil, Peru, Colombia, French Guiana (Uetz 2005. http://www.reptile-database.org). Present records extend known distribution 432 km S from Nova Brasil in Brazil (Vanzolini 1986. Levantamento Herpetologico da Área do Estado de Rondônia sob a Influencia da Rodovia BR 364: Relatorio de Pesquisa, Rio de Janeiro 1:1–50). Vanzolini does not mention specimens but according to Carolina Mello (MZUSP, pers. comm.) it should be museum specimen MZUSP 8519 from Ribeirão Riachuelo.

New Records and Type Locality Restriction for the Endemic Argentinian Lizard *Cnemidophorus tergolaevigatus* (Squamata: Teiidae)

MARIO R. CABRERA
CONICET Researcher, Departamento Diversidad Biológica y Ecología
Universidad Nacional de Córdoba, Vélez Sarsfield 299
X5000JJC Córdoba, Argentina
e-mail: mcabrera@efn.uncor.edu

and

RICHARD E. ETHERIDGE
Department of Biology, San Diego State University
San Diego, California 92182-4614, USA
e-mail: rether@sunstroke.sdsu.edu

With the recent description of *Cnemidophorus tergolaevigatus* (Cabrera 2004) it has become evident that most of the previous records north to 30°S of *C. longicauda* (e.g., Cei 1993; Peters and Donoso-Barros 1970; Reeder et al. 2002) probably refer to the new species. Here we provide new locality records that extend the range of this species both northward and southward of those listed in the original description, adding three new provinces to La Rioja. Additionally, we also here restrict the type locality of *C. tergolaevigatus*.

Specimens housed at the Centro Nacional Patagónico-Conicet, Puerto Madryn, Argentina (LJAMM) and the Fundación Miguel Lillo, Tucumán, Argentina (FML) have been verified by M. Chiaraviglio, and those housed at San Diego State University, San Diego, California, (SDSU) and the American Museum of Natural History, New York (AMNH) have been verified by T. Reeder. MACN is the acronym of Museo Argentino de Ciencias Naturales, Buenos Aires, Argentina.

First Department record.

SALTA PROVINCE: CAFAYATE DEPT.: Los Médanos, 0.5 km E Ruta nacional 68 and 6.7 km from junction of routes 68 and 40. 1650 m elev. (26°04'00.4"S, 65°54'38.2"W). 4 January 1991. R. Espinoza. FML 03552. First province record, and northernmost vouchered locality for the species.

TUCUMÁN PROVINCE: TAFÍ DEPT.: Between Santa María and Amaicha del Valle. 2 January 1989. R. Etheridge. SDSU 2438–39; AMNH R-144526–27. First province record.

Type locality restriction.—At the time of the description of *Cnemidophorus tergolaevigatus* the exact location from which the holotype and paratypes were obtained was unknown. According to entries in the MACN catalog these specimens were collected during a field trip to western Argentina in the austral summer of 1933–1934, in which the villages of Chilecito and Villa Unión, as well as Sierras of Famatina and Velasco, were visited. Other specimens of reptiles and anurans obtained during this expedition share the same provenance. Now that we know more accurately the present range of this species, we believe it is appropriate here to restrict its type locality. Therefore, in compliance with the International Code of Zoological Nomenclature (ICZN 1999, Article 76A.1.4) we here restrict the type locality of *Cnemidophorus tergolaevigatus* to Chilecito, in Chilecito Department, La Rioja province, Argentina.

Comments.—*Cnemidophorus tergolaevigatus* was previously known only for localities in the Argentinean province of La Rioja (Cabrera 2004). With the present records the northwestern provinces of Catamarca, Tucumán, and Salta are added to the range of the species, extending its distribution northward up to 26° south latitude.

Cnemidophorus tergolaevigatus and *C. longicauda* are endemic to Argentina, and are the only members of the *longicauda* species group (Cabrera 2004). The presence of individuals showing intermediate characteristics syntopic with both species of the group, collected at Coronel Felipe Varela Department in La Rioja province, as well as at near sites in Catamarca province (unpubl. data) suggests hybridization, a common phenomenon in the genus (Wright 1993) deserving further study.

Acknowledgments.—Thanks to Luciano Avila (LJAMM), Gustavo Carrizo (MACN), Sonia Kretzschmar and Esteban Lavilla (FML) for the loan of specimens, and Margarita Chiaraviglio and Tod Reeder for verifying specimens. Funding was provided through grants to MRC by the Secretaría de Ciencia y Tecnología, Universidad Nacional de Córdoba, Argentina (SeCyT-UNC).

e-mail: herpetofauna3@yahoo.com

The geographic distribution of the herpetofauna of Texas is well documented (Dixon 2000). However, many counties in northeast Texas have not been sampled adequately, and the occurrence of several common species has not previously been documented. The following records provide new information regarding the geographic distribution of reptiles and amphibians in three counties in northeast Texas. New records were obtained while conducting a baseline inventory of reptiles and amphibians at Camp Maxey Army Base in Lamar County, Texas, as well as recent collecting efforts by the authors. All specimens were captured using time constraint searches, road cruising, cover board surveys, and minnow traps. All voucher specimens are deposited in the University of Texas at Arlington Amphibian and Reptile Research Diversity Center. All records represent new occurrences in their respective counties, based on Dixon (2000).

Caudata

Ambystoma maculatum (Spotted Salamander). LAMAR CO.: Found under rotten log on the edge of a bog in bottomland deciduous hardwood forest on the grounds of Camp Maxey Army Base,

Powderly, Texas (33°48'77"N; 95°32'73"W). 8 February 2003. Collected by B. E. Fontenot. Verified by Jonathan A. Campbell. Slide No. 31351. First county record. Previously reported from adjacent Red River Co.

Notophthalmus viridescens (Eastern Newt). LAMAR Co.: Captured by dip netting a small pond near disturbed prairie and bottomland deciduous hardwood forest on the grounds of Camp Maxey Army Base, Powderly, Texas (33°48'77"N; 95°32'73"W). 11 December 2002. Collected by R. Brenes. Verified by Ronald L. Gutberlet Jr. UTA A-56755. First county record. Previously reported from adjacent Red River Co.

Siren intermedia (Lesser Siren). LAMAR Co.: Found in minnow trap placed in small pond near disturbed prairie and bottomland deciduous hardwood forest on the grounds of Camp Maxey Army Base, Powderly, Texas (33°48'77"N; 95°32'73"W). 8 January 2003. Collected by V. Adams. Verified by Ronald L. Gutberlet, Jr. UTA A-56747. First county record. Previously reported from adjacent Delta Co.

Anura

Hyla cinerea (Green Tree Frog). MARION Co.: Large breeding chorus in lakeside vegetation at Potter's Point Marina, Boat Ramp 3644 off FM 727 (32°42'19"N; 94°04'25"W). 21 June 2002. Collected by S. Morrison. Verified by Ronald L. Gutberlet Jr. UTA A-56664. First county record. This specimen fills a gap in the distribution of this species in eastern Texas.

Hyla versicolor (Gray Tree Frog). LIMESTONE Co.: AOR, intersection of FM 1512 and NW Hwy 79, ca. 6.2 km W of Jewett, Texas (31° 20'3"N; 96°10'62"W). 26 June 2002. Collected by B. E. Fontenot . Verified by Ronald. L. Gutberlet Jr. UTA A-56665. First county record. This specimen fills a gap in the distribution of this species and was previously reported from adjacent Navarro, Freestone, Leon, Robertson, Falls, Mclennan, and Hill counties.

Rana areolata (Southern Crawfish Frog). LAMAR Co.: Breeding chorus at small pond in disturbed prairie habitat on the side of FM 1499 ca. 5 km N of Pat Mayse Lake, Powderly, Texas (33°49'92"N; 95°31'42"W). 6 March 2004. Collected by B. E. Fontenot. Verified by Jonathan A. Campbell. UTA A-56666. First county record. Previously reported from adjacent Red River and Fannin counties.

Lacertilia

Hemidactylus turcicus (Mediterranean House Gecko). LAMAR Co.: Found on side of building on the grounds of Camp Maxey Army Base, Powderly, Texas (33°62'72"N; 95°33'87"W). 25 July 2002. Collected by B. E. Fontenot. Verified by Ronald L. Gutberlet, Jr. UTA R-52877. First county record. This specimen represents a northeastern extension of the range of this species in Texas and was not previously reported in any adjacent counties.

Ophisaurus attenuatus (Slender Glass Lizard). LAMAR Co.: Under wooden cover board located on the edge of a disturbed prairie and bottomland deciduous hardwood forest on the grounds of Camp Maxey Army Base, Powderly, Texas (33°47'92"N; 95°34'46"W). 15 May 2003. This site was burned by a naturally occurring forest fire two days prior to the date of collection. Collected by B. E. Fontenot. Verified by Ronald L. Gutberlet, Jr. UTA R-52876. First county record. Previously reported from adjacent Red River and Fannin counties.

Universidade do Estado do Rio de Janeiro, Rua São Francisco Xavier
524, Maracanã, 20550-019, Rio de Janeiro, RJ, Brazil
e-mail (CFDR): cfdrocha@uerj.br

Ilha Grande, a continental island located in the southern coast of Rio de Janeiro State (Angra dos Reis Municipality) (23°15'S; 44°15'W) in Brazil, is one of the largest continuous remnants of the Atlantic rainforest in the State of Rio de Janeiro. Most of its 19,300 ha is covered by habitats characteristic of this biome (e.g., undisturbed dense forest, secondary forest, "restinga"s—coastal sand dune habitats—and mangroves). The remnants of the Atlantic Rainforest at Ilha Grande consist of a mosaic of forests with different levels of regeneration due to disturbances caused by human activities over the last three centuries. In the past the area was an important region for coffee, corn, and sugar plantations. Farming ceased when the area became a state park (Araújo and Oliveira 1988). Some remnants of primary forest can still be found in the most inaccessible central areas of the island. Annual rainfall in the area is about 1700 mm and mean annual temperature is about 23°C. During the last decade an increase in human activites have imperiled some habitats on the island (Alho et al. 2002). Despite being one of the most important remnants of the Brazilian Atlantic Rainforest, only three published reports regarding reptile species for Ilha Grande exist: Jackson (1978) noted a specimen of *Enyalius brasiliensis brasiliensis*; Rocha et al. (1999) reported on prey of the colubrid *Chironius multiventris foveatus*; and Van Sluys and Rocha (1999) described the activity of the teiid lizard *Tupinambis merianae*.

Since 1995, surveys on Ilha Grande carried out by personnel of the Departamento de Ecologia of the Instituto de Biologia of the Universidade do Estado do Rio de Janeiro have resulted in the accumulation of records of reptiles occurring on the island. Except for *C. m. foveatus*, *E. brasiliensis*, and *T. merianae*, the reptile species listed below represent the first published records for Ilha Grande. Measurements of lizards are presented in mm and those of snakes in cm. At each site where a reptile was collected, we recorded, whenever possible, the geographic position (using a Garmin III GPS) and elevation (using an altimeter). Because no voucher specimen of *T. merianae* at Ilha Grande had previously been collected (Van Sluys and Rocha 1999), here we include a record for the species supported by a voucher specimen. We also

include a recent voucher specimen of *Enyalius brasiliensis*.

Our report increases the number of reptiles species known from Ilha Grande to 25, including nine lizards and 16 snakes. All of the species found were expected, based on the previously known geographic distribution. Voucher specimens were deposited at the Museu Nacional, Rio de Janeiro (MNRJ). Ronaldo Fernandes, Curator, Department of Vertebrates, MNRJ, identified all specimens, with the exception of *Chironius exoletus* and *Xenodon newiedii*, which were identified by Daniel S. Fernandes of MNRJ.

Lacertilia

Diploglossus fasciatus. Vila dos Dois Rios Village. 4 April 1997. C. F. D. Rocha and M. Van Sluys. MNRJ 9782. Adult female (278.8 mm TTL; 120.3 mm SVL) collected in a garden (ca. 5 m elev.) (23°10'79.5"S, 44°10'68.8"W); Aventureiro Village. February 2001. Unknown collector. MNRJ 9783. Adult male (154.0 mm TTL; 91.0 mm SVL) collected in the secondary forest (23°10'49.3"S, 44°18'74.1"W).

Ecpleopus gaudichaudii. Vila dos Dois Rios Village. 15 September 1996. C. F. D. Rocha and M. Van Sluys. MNRJ 9792. Juvenile male (89.6mm TTL; 31.3 mm SVL) . On leaf litter (1230 h) at an undisturbed forest area (ca. 240 m elev.) (23°10'55.9"S, 44°12' 49.8"W). Mean leaf litter depth at collecting site was 77.1 ± 21.1 mm and litter temperature was 19.0°C.

Enyalius brasiliensis. Vila dos Dois Rios Village. 21 January 1996. C. F. D. Rocha and M. Van Sluys. MNRJ 9794. Adult gravid female (252.6 mm TTL; 100.6 mm SVL; clutch size = 10). On liana (20 mm diameter) 60 cm above ground (1115 h) at the secondary forest near the Mãe D'Água Dam (ca. 110 m elev.) (23°10'92.3"S, 44°12'04.4"W).

Gymnodactylus darwinii. Vila dos Dois Rios Village. 26 January 2000. M. Van Sluys and F. H. Hatano. MNRJ 9790. Adult male (78.3 mm TTL; 44.9 mm SVL; body temperature: 26.4°C; air temperature: 27.0°C). On the ground (1256 h) in secondary forest near the Barra Pequena River (ca. 5 m elev.) (23°11'30.7"S, 44°12"68.5"W).

Hemidactylus mabouia. Vila dos Dois Rios Village. 3 December 1998. C. F. D. Rocha and M. Van Sluys. MNRJ 9784. Juvenile (44.0 mm TTL; 24.5 mm SVL). On liana 2 m above ground (1453 h) in secondary forest near to the Barra Grande River (ca. 10 m elev.), along the trail linking Vila dos Dois Rios Village to Parnaioca beach (23°10'02.6"S, 44°09'20.1"W).

Leposternon microcephalum. Vila dos Dois Rios Village. 1 November 1998. C. F. D. Rocha and M. Van Sluys. MNRJ 9788. Adult male (287.2 mm TTL; 16.5 cm SVL) collected near urban area (at sea level) (23°10'62.4"S, 44°10'13.0"W), moving on ground after heavy rain.

Mabuya agilis. Praia do Sul. 14 February 2001. D. Vrcibradic. MNRJ 9789. Adult gravid female (111.0 mm TTL; 77.6 mm SVL; specimen presenting a broken tail) (5 ova in oviducts). Moving on the ground in the leaf litter in restinga habitat of Praia do Sul (ca. 5 m elev.) (23°10'32.0"S, 44°17'85.0"W); Vila dos Dois Rios Village. 12 January 1997. D. Vrcibradic and C. A. Cardozo. MNRJ 9494–9498. Juveniles (range 46.3–92.4 mm TTL; 33.8–41.5 mm SVL; all juveniles were found moving on the ground among the grass (ca. 5 m elev.) (23°10'74.3"S, 44°10'77.4"W).

Placosoma glabellum. Vila dos Dois Rios Village. December 1996. Received by C. F. D. Rocha from an island inhabitant who collected the specimen in secondary forest. MNRJ 9797. Adult male (72.0 mm TTL; 45.0 mm SVL; broken tail).

Tupinambis merianae. Vila dos Dois Rios Village. 10 October 2002. H. G. Bergallo. MNRJ 9772. Sub-adult male (745.0 mm TTL; 245.0 mm SVL; body mass 490 g) collected after being killed by a dog in urban area (ca. 5 m elev.) (23°10'76.9"S, 44°10'78.1"W).

Serpentes

Bothrops jararaca. Vila dos Dois Rios Village. 24 November 2001. M. A. Gomes and A. R. M. Azevedo. MNRJ 9786. Female (63.2 cm TTL; 53.8 cm SVL) collected on leaf litter bordering a temporary pond (2100 h) in secondary forest area (ca. 25 m elev.) along the trail linking Vila dos Dois Rios Village to Parnaioca beach (23°11'04.9"S, 44°11'77.6"W).

Bothrops jararacussu. Vila dos Dois Rios Village. 12 October 1996. E. Brito. MNRJ 9787. Juvenile female (42.3 cm TTL; 37.5 cm SVL) found under debris on grass-covered ground (at sea level) in the Central Square of the village (23°10'87.5"S, 44°10'63.0"W).

Chironius bicarinatus. Vila dos Dois Rios Village. 12 September 1999. C. F. D. Rocha and M. Van Sluys. MNRJ 9773. Adult female (129.0 cm TTL; 81.0 cm SVL) moving on ground at 0937 h under herbaceous vegetation in an area of undisturbed forest (ca. 230 m elev.) (23°10'71.5"S, 44°10'06.2"W); Caxadaço beach.19 April 1997. C. F. D. Rocha. MNRJ 9774. Adult male (169.3 cm TTL; 105.2 cm SVL) moving on ground at 1410 h along the trail to Caxadaço beach in secondary forest (ca. 30 m elev.) (23°09' 73.4"S, 44° 08'89.6"W); 9 February 1996. C. F. D. Rocha. MNRJ 9795. Juvenile female (34.1 cm TTL; 23.2 cm SVL) moving on ground in secondary forest area along the dirt road linking Vila do Abrahão to Vila dos Dois Rios Village (23°09'81.2"S, 44°08'13.3"W).

Chironius exoletus. Vila dos Dois Rios Village. 4 November 2002. Collected by an unknown island inhabitant. MNRJ 9799. Adult female (120.0 cm TTL; 78.0 cm SVL) found on grass-covered ground at the urban area of the Village (at sea level).

Chironius multiventris foveatus. Vila dos Dois Rios Village. 8 December 1996. C. F. D. Rocha. MNRJ 6717. Adult male (207 cm TTL; 129 cm SVL) collected in an undisturbed Atlantic Rainforest area (ca. 240 m elev.) (23°10'55.8"S, 44°12'49.9"W). The snake was moving over large boulders near a subterranean stream (see Rocha et al. 1999).

Clelia plumbea. Vila dos Dois Rios Village. 12 December 1998. C. F. D. Rocha. MNRJ 9791. Juvenile female (59.4 cm TTL; 9.4 cm SVL) moving on ground in secondary forest area (ca. 120 m elev.) along the trail to the Mãe D'Água Dam (23°10'81.6"S, 44°12'25.2"W).

Imantodes cenchoa. Vila dos Dois Rios Village. 26 November 2000. M. Rico. MNRJ 9777. Juvenile female (68.5 cm TTL; 48.7 cm SVL) collected at Barra Pequena River (23°10'90.6"S, 44°10' 20.4"W) near the village at sea level. The snake was on vegetation 1 m above a stream.

Liophis miliaris. Vila dos Dois Rios Village. 13 February 1997. E. Silva. MNRJ 9781. Juvenile (25.0 cm TTL; 21.5 cm SVL) col-

lected in a swamp area adjacent to the Estrada das Palmeiras in the village surroundings (23°10'67.3"S, 44°10'29.0"W).

Liophis poecilogyrus. Vila dos Dois Rios Village. 12 October 1996. C. F. D. Rocha. MNRJ 9780. Adult male (66.8 cm TTL; 54.0 cm SVL) collected when moving on the ground (1800 h) in secondary forest along the trail to the Mãe D'Água Dam (23°10'99.0"S, 44°12'12.5"W).

Micrurus corallinus. Parnaioca Beach. 17 October 1999. C. F. D. Rocha. MNRJ 9778. Adult female (61.4 cm TTL; 51.3 cm SVL) collected in secondary forest (ca. 40 m elev.) along the trail linking Parnaioca beach and Vila dos Dois Rios Village (23°11'79.6"S, 44°14'17.6"W). The snake was moving (1140 h) on the ground under herbaceous vegetation.

Oxyrhopus clathratus. Vila dos Dois Rios Village. 16 May 1997. C. F. D. Rocha. MNRJ 9776. Adult male (85.0 cm TTL; 68.8 cm SVL). Moving on ground under herbaceous vegetation (1940 h) in secondary forest near Mãe D'Água Dam (ca. 60 m elev.) (23°10' 92.3"S, 44°12'04.4"W).

Sibynomorphus newiedi. Vila dos Dois Rios Village. 16 August 1997. C. F. D. Rocha. MNRJ 9785. Adult female (59.9 cm TTL; 47.6 cm SVL) found on ground under a shrub (1530 h) in secondary forest (ca. 15 m elev.) (23°10'57.5"S, 44°11'79.1"W).

Siphlophis pulcher. Vila dos Dois Rios Village. 14 December 1997. C. F. D. Rocha. MNRJ 9775. Adult male (83.5cm TTL; 62.5 cm SVL) collected on leaf of a coconut palm, 4 m above ground in secondary forest area, at sea level (23°11'09.9"S, 44°11'45.6"W).

Spilotes pullatus. Vila dos Dois Rios Village. 17 November 1998. C. B. Lemos. MNRJ 9779. Juvenile (49.1 cm TTL; 37.3 cm SVL) collected in undisturbed Atlantic Rainforest (ca. 210 m elev.) on a branch of a shrub. (23°10'55.8"S, 44°12'49.9"W).

Thamnodynastes cf. *strigilis*. Vila dos Dois Rios Village. 30 October 2000. C. F. D. Rocha and M. Van Sluys. MNRJ 9793. Adult female (68.0 cm TTL; 51.8 cm SVL; 46.3 g; body temperature: 21.2°C; air temperature: 23.0°C) on leaf litter at bottom of dried temporary pond (1627 h) in secondary forest along trail to Parnaioca beach (ca. 10 m elev.) (23°10'98.5"S, 44°12'49.8"W).

Xenodon newiedii. Vila dos Dois Rios Village. 5 November 2002. Collected by an unknown island inhabitant. MNRJ 9800. Adult male (57.6 cm TTL; 47.0 cm SVL) collected on ground covered with grass and shrubs at the urban area of the village (at sea level).

Acknowledgments.—This study is part of the BIOTA/FAPESP Project (process No. 99/08291-5), and was also partially supported by grants of the Conselho Nacional do Desenvolvimento Científico e Tecnológico (CNPq) to CFDR (processes 307653/2003-0 and 477981/2003-8) and to MVS (Process 301117/95-0). Centro de Estudos Ambientais e Desenvolvimento Sustentável (CEADS) of the Universidade do Estado do Rio de Janeiro at Ilha Grande provided local logistic support. We are grateful to many of our students who provided field assistantship along the Project. D. Vrcibradic and D. M. Peccinini-Seale revised the manuscript, and D. Vribradic helped with laboratory assistantship.

and

JOHN J. MORIARTY
Bell Museum of Natural History, University of Minnesota
10 Church St. S.E., Minneapolis, Minnesota 55455, USA

We examined recent amphibian and reptile specimens and photos deposited in the amphibian and reptile collection of the Bell Museum of Natural History (JFBM) and provide a list of new amphibian and reptile county records in Minnesota (Moriarty 1996; Oldfield and Moriarty 1994). The majority of new records were due to collecting efforts related to the Minnesota Dept. of Natural Resources' Minnesota County Biological Survey. Andrew M. Simons verified all specimens and photos. JFBM specimen numbers preceded by a "P" are cataloged in the photo collection. Nomenclature follows Crother (2000) except where noted.

Caudata

Ambystoma laterale (Blue-spotted Salamander). Kandiyohi Co.: Sibley State Park (45°18'48"N, 95°01'28"W). 20 May 1996. M. Carroll. JFBM P221. Wright Co.: Lake Maria State Park (45°19'30"N, 93°57'06"W). 10 June 2001. T. Gamble. JFBM P249.

Ambystoma tigrinum (Tiger Salamander). Lyon Co.: Prairie Marshes Wildlife Management Area, (44°21'45"N, 95°58'14"W). 29 June 19696. R. Lehtinen. JFBM 13532. Pope Co.: Wetland 1 mile N of Rocky Mountain Lake (45°25'17"N, 95°12'08"W). 2 July 1996. R. Lehtinen. JFBM 13677. Todd Co.: Wetland 3 miles S of Long Prairie, (45°55'27"N, 94°52'51"W). 3 July 1996. R. Lehtinen. JFBM 13679.

Hemidactylium scutatum (Four-toed Salamander). Carlton Co.: Nemadji State Forest along Harris Forest Rd, (46°26'01"N, 92°19'49"W). 4 May 1999. G. Casper. JFBM 14161. Adult. Nemadji State Forest along Harris Forest Road (46°26'01"N, 92°19'49"W). 4 May 1999. G. Casper. JFBM 14183. 3 eggs. Itasca Co.: Chippewa National Forest (47°27'05"N, 93°39'07"W). 22 August 1994. C. Dorff Hall & Suddendorf. JFBM 13472. Chippewa National Forest (47°27'05"N, 93°39'07"W). July 1995. J. LeClere.

JFBM 13568. Mille LACS Co.: Mille Lacs Kathio State Park (46°07'07"N, 93°42'59"W). 11 May 1999. LeClere. JFBM 14194. PINE Co.: St. Croix State Forest, E of Mcdermott Creek (46°05'4"N, 92°28'06"W). 5 May 1999. G. Casper. JFBM 14160. St. Croix Sate Forest, SE of Rock Lake access (46°02'50"N, 92°25'08"W). 9 May 1999. G. Casper. JFBM 14162. Nemadji State Forest (46°18'54"N, 92°20'05"W). 6 May 1999. G.Casper. JFBM 14198.

Necturus maculosus (Mudpuppy). DOUGLAS Co.: Lake Latoka in boulder rip-rap under Interstate 94 bridge (45°51'53", 95°26'08"). 24 May 2005. K Schmidt. JFBM 14411–14412, 14414. KANABEC Co.: Knife Lake (45°58'07"N, 93°18'20"W). 11 October 1989. K. Schmidt. JFBM 13355.

Notopthalmus viridescens (Eastern Newt). CHISAGO Co.: Taylors Falls (45°24'41"N, 92°39'06"W). 19 Apr 1980. D. Hanych. JFBM 13882. ITASCA Co.: Chippewa National Forest (47°27'05"N, 93°39'07"W). July 1995. J. LeClere. JFBM 13569–13570.

Anura

Bufo americanus (American Toad). CARVER Co.: Hwy 7 near Hollywood (44°54'23"N, 93°58'53"W). 16 May 1999. T. Gamble. JFBM 14188. CHIPPEWA Co.: Flooded field NW of Milan (45°06'53N, 95°56'19"W). 23 May 2003. T. Gamble, P. Berendzen, and B. Nagle. JFBM 14317–14320. MEEKER Co.: Hwy 21 N of Big Swan Lake (45°09'37"N, 94°15'38"W). 16 October 1996. R. Blasus and J. LeClere. JFBM 13910–13911. Hwy 7 W of Cedar Mills (44°56'29"N, 94°34'13"W). 16 May 1999. T. Gamble. JFBM 14189. WRIGHT Co.: Wetland near entrance of Lake Maria State Park (45°19'01"N, 93°56'03"W). 26 May 2003. T. Gamble and B. Nagle. JFBM 14326.

Bufo cognatus (Great Plains Toad). RENVILLE Co.: NW of Renville (44°49'50"N, 95°14'28"W). 8 June 1999. C. Dorff Hall and T. Gamble. JFBM 14144.

Bufo hemiophrys (Canadian Toad). YELLOW MEDICINE Co.: Sioux Nation Wildlife Management Area (44°40'54"N, 96°26'08"W). June 1996. R. Lehtinen. JFBM P245.

Hyla chrysoscelis (Cope's Gray Treefrog). CARVER Co.: Spring Peeper Meadow, University of Minnesota Arboretum, (44°51'25"N, 93°35'08"W). 20 May 1998. R. Lehtinen. JFBM 13734. Calling male. Restored wetland N of Waconia (44°51'42"N, 93°49'51"W). 25 May 1998. R. Lehtinen. JFBM 13747. Calling male. CASS Co.: S of Oshawa (46°43'28"N, 94° 32'14"W). 20 June 1994. C. Dorff Hall and S. J. Presley. JFBM 14084. FILLMORE Co.: N of York (43°32'36"N, 92°16'43"W). 11 June 1996. C. Dorff Hall and C. Van Gorp. JFBM 14071. Calling male. NICOLLET Co.: Wetland in Swan-Oshawa Wildlife Management Area (44°19'33"N, 94°06'44"W). 19 May 1998. R. Lehtinen. JFBM 13750. Calling male. STEELE Co.: Restored wetland adjacent to Straight Creek (43°53'45"N, 93°10'10"W). 27 May 1998. R. Lehtinen. JFBM 13733. Calling male. Restored wetland South of Straight Creek (43°53' 45"N, 93°11'48"W). 27 May 1998. R. Lehtinen. JFBM 13742. Calling male. OTTERTAIL Co.: County Hwy 128 at El Will Road (46°21'38", 95°37'56"W). 14 June 2003. B. Nagle. JFBM 14355. Calling male.

Hyla chrysoscelis/versicolor (Gray Treefrog). MCLEOD Co.: Highway 7 near Lester Prairie (44°54'23"N, 94°05'46"W). 16 May 1999. T. Gamble. JFBM 14184. MEEKER Co.: Highway 7 W of Cedar Mills (44°56'29"N, 94°34'27"W). 16 May 1999. T. Gamble. JFBM 14185. TODD Co.: Wetland 1 mile NE of Bunker Lake (45°49'28"N, 94°50'14"W). 15 July 1996. J. Husveth. JFBM 13683.

Hyla versicolor (Gray Treefrog). CARVER Co.: Restored wetland N of Waconia (44°51'42"N, 93°49'51"W). 5 May 1998. R. Lehtinen. JFBM 13736. Calling male.

Pseudacris crucifer (Spring Peeper). MARSHALL Co.: Near Red Lake Indian Reservation (48°29'06"N, 94°46'54"W). 9 August 1992. S. J. Presley. JFBM 13962. ST. LOUIS Co.: Ketagama Lake, Voyageurs National Park (48°28'07"N, 92°52'38"W). 9 August 1998. Palmer. JFBM 13352.

Pseudacris maculata (Boreal Chorus Frog). CARVER Co.: Spring Peeper Meadow, University of Minnesota Arboretum (44°51'25"N, 93°35'08"W). 5 June 1998. R. Lehtinen. JFBM 13732. Malformed. Given that the majority of the world's reptile species are oviparous (Zug et al. 2001), one could be excused for assuming that the environmental influence of incubation in reptiles had been comprehensively covered long ago. However, while the captive effects of incubation in reptiles have been explored recently (Köhler 1997), this treatment provides little evidence of potential environmental effects. *Reptilian Incubation* fills this void by examining the environmental effects of incubation and their implications for the evolution and behavior of reptiles. In short, this book aims to develop a comprehensive understanding of the way eggs are incubated outside the maternal body. Arranged in three parts, the book deals with how the incubation environment affects nests, eggs and embryos, and the repercussions of any long-term effects for reptilian biology.

In Chapter One, Deeming and Unwin focus on the origin and evolution of the reptilian amniotic egg, and review the evidence for reptilian incubation in the fossil record. They highlight important evolutionary stages in the development of eggs, egg shells, nests and the implications for embryos. The negative relationship between the degree of egg shell calcification and gas conductance means that, with some knowledge of egg shell formation and egg composition, it is possible to gain an idea of the nest environment in which many taxa evolved. In general, the eggs of lepidosaurs (with the exception of some geckos) and *Sphenodon* are poorly calcified and require moist environments, whereas the more extensively calcified eggs of chelonians and crocodilians are less reliant on external water for incubation. While the fossil egg record is limited to relatively few taxa, many of which are dinosaurs, it does provide a useful starting point for inferring the ovipositional environments in which these taxa evolved. The presence of fully formed embryos in the abdominal cavity of a mosasaur fossil strongly suggests that some forms were probably viviparous (Caldwell and Lee 2001), and that the fossil record can provide insight into the evolution of novel traits.

Ackerman and Lott (Chapter Two) focus on the thermal, hydric and respiratory environments likely to occur in soils surrounding buried and incubating reptile eggs, with a major focus on chelonians. The authors acknowledge that there are relatively few available data describing these variables for incubating eggs and offer at least one possible shortcut — the use of data from climatic archives, many of which are available on the web. Such data should provide a general starting point for those intending to examine species for which actual nest temperature data are unavailable or incomplete. Data on the temperatures experienced by eggs in natural nests is still scarce, but this situation appears to be changing rapidly (e.g., Shine and Harlow 1996). However, there remains a need for appropriate long-term measures of temperatures of the soil surrounding reptile nests incorporating techniques from soil science.

Thompson and Speak examine the morphology and composition of modern reptile eggs (Chapter Three). Separate descriptions place emphasis on those features salient to each lineage, with comparisons to birds. Data from all known studies detailing egg chemical compositions are clearly displayed in a series of tables. In summary, while the lipid, protein and energy content is generally similar across taxa (mean lipid : protein ratio 2:1), the evolution of the reptilian egg from that of amphibians was accompanied by a proportional increase in protein. Interestingly, the proportion that certain lipids occur in the eggs of several scincids differs from that in the maternal diet, and possibly reflects what remains of a phylogenetically conserved trait or dietary shift in these taxa.

In Chapter Four, Andrews discusses patterns of embryonic development with reference to the "evo-devo" (evolution and development) debate and the role of developmental biology and regulatory genes (e.g., Hox genes) in determining morphological traits and body plans (West-Eberhard 2003). Andrews reviews the qualitative and quantitative aspects of embryonic development, developmental arrest, egg and nest emergence, and factors affecting hatchling size. While both reptile and bird development are highly conservative, biologically significant differences do exist among reptiles. Hox and other genes associated with development provide some evidence for the absence of forelimbs and the reduction in limb size in various limb-reduced taxa. Another trend is for the chorioallantoic membrane to change size in response to the degree of water uptake and egg surface area in squamates, but remain of a fixed size in rigid shelled taxa (e.g., chelonians, crocodilians, etc.). In general, the earlier stages of development are most sensitive to temperature, with low temperatures and moist conditions producing larger hatchlings, with a relatively low proportion of residual yolk. One interesting consequence of the thin permeable shell of squamate eggs, which facilitates gaseous and fluid exchange *in utero*, may provide a mechanistic explanation for why viviparity has evolved so frequently in this lineage.

Birchard (Chapter Five) reviews the effects of temperature on embryonic development. Specifically, the thermal environment, the temperatures tolerated and a description of the effects of temperature on growth and physiological rates. Birchard incorporates

much additional information since the publication of earlier reviews of reptilian incubation (Deeming and Ferguson 1991; Ackerman 1994). In general reptile nests typically occur in sites where eggs experience a non-lethal range of temperatures. One interesting distinction being that between developmental period and incubation period — the former referring to the period during which temperatures exceed the minimum suitable for development; the latter to the overall period from laying to hatching. Strangely, despite the biological relevance of this distinction it has rarely been used. Further evidence for the importance of defining those temperatures experienced in natural nests comes from the effect of out-of-phase oscillations between surface soil and the deeper soil surrounding the nest, which can have important consequences for water and respiratory gas exchange in eggs.

In Chapter Six, Belinsky, Ackerman, Dmi'el and Ar, explore the delicate balance between the various environmental factors to which reptile eggs are exposed. Thus, while initial water content varies among taxonomic groups and environmental conditions, under most incubation and hydric conditions the majority of yolk-free hatchlings have relatively similar water content. Similarly, variation in egg shell types leads to equally varied changes in hydric conditions, with some lizard eggs gaining more than three times the original mass during incubation! Data are summarized in several tables presenting wet and dry egg masses. Compared to other taxa lizards typically have higher hatchling wet mass to egg wet mass ratios. Clearly, egg size and shell type are important for initial egg water concentrations. It seems likely that the plasticity of reptilian nest-site selection along with incubation conditions that affect the mass and water content of hatchlings and residual yolk have played a major role in reptilian evolution.

The same authors follow on with the longest chapter (Chapter Seven, 42 pages, 8 Tables, 7 Figures), presenting new and published data on energy density values for the components of reptilian eggs and hatchlings (26 species), as well as new data on oxygen consumption (25 species). Indeed, much of this chapter is taken up with data presented in tables and figures. They indicate that reptiles are a homogeneous group in terms of energy use, relative to birds, which exploit a wide range of incubation temperatures. An interesting finding being the similar mass-specific energy use efficiency of reptiles and birds, which appears suggestive of their common ancestry. However, compared to other reptiles, lizards differ as a group due to their greater oxygen-use efficiency.

Shine (Chapter Eight) examines the effects of the nest environment of squamate reptiles, using much of his data to explore the adaptive role of maternal exploitation of embryonic sensitivity, and in particular the role it has played in the evolution of maternal behavior and physiology. Specifically, where incubation-induced effects are of sufficient magnitude and duration to substantially affect offspring fitness, they are also likely to have a significant role in the evolution of maternal behavior and physiology. As such, there is a real need to identify those traits potentially under maternal control (e.g., nest site selection). The review begins with a description of those traits found within squamates (the group with the greatest range of reproductive traits), before incorporating information on other reptile groups and comparing forms of maternal manipulation of offspring phenotypes. Shine also highlights areas of future importance, including the use of intraspecific comparative studies to detect microevolutionary processes, defining and verifying the link between phenotypic traits and fitness, and using incubation conditions that resemble those of natural nests (Shine and Harlow 1996). Indeed, such studies may also be informative with respect to other adaptive processes (e.g., Temperature-dependent sex determination, TSD; Elphick and Shine 1999). While the effects of nest temperature on hatchling size, shape and locomotor performance may have important fitness consequences such effects may be offset if hatching occurs during a less favorable period. Nonetheless, while there is a need to mimic the conditions of natural nests in studies of the evolution of maternal manipulation of hatchling phenotypes, whether studies of other evolutionary phenomena based on constant temperature incubation are any less informative may be dependent on the system examined (e.g., Vanhooydonck et al. 2001; Kearney and Shine 2004). The next portion of the book focuses on the effects of incubation on TSD. In short, because reptiles possess both genotypic-sex determination (GSD) and TSD they are ideal for comparative studies of sex determination in vertebrates (Bull 1980). Valenzuela (Chapter Nine) focuses on how the environment affects sex determination from the thermal and biochemical standpoint in reptiles, with a consideration of the evolution of TSD. A large table provides details of species from families for which TSD is known and for which it is absent. Unfortunately, while a search using comparisons of thermal, physiological and molecular mechanisms of both TSD and GSD seems promising, they offer little insight into those factors occurring in nature. Nonetheless, Valenzuela provides several testable predictions for the evolution of TSD, including examples of conditions under which TSD is unlikely to occur. Despite the large number of examples, conclusive evidence of an adaptive explanation of TSD in vertebrates is known only from one species each of fish and lizard. Yet, while this is an extensive list of criteria the prospect that a species may have more than one explanation of TSD ensures that this will remain a challenging area of research (Valenzuela et al. 2003).

In Chapter Ten, Deeming reviews the post-hatching effects of incubation on reptile phenotypes. Laboratory and field studies indicate that the incubation environment of reptile eggs affects a wide variety of post-hatching traits including morphology, physiology and behavior. He also proposes that at present relatively few trends can be drawn from most taxonomic groups, as conclusions have typically been biased toward a few well studied species. Further, there remains the possibility that life histories of individual species may be important in the expression of post-hatching phenotypes, with the suggestion of future work increasing the current species database to identify trends and those physiological mechanisms that influence the phenotype long after hatching. Clearly, identifying incubation regimes for which post-hatching performance is compromised will have major value for conservation and management programs.

In the shortest chapter (Chapter Eleven; 11 pages), Booth reviews the role of artificial incubation for both experimental and captive research, and covers obtaining eggs, the movement of eggs, incubation temperatures, hydric conditions and microbial infections. In general, most reptile eggs incubate over a wider range of temperature than birds (e.g., 5–8°C). For maximal hatching success, Booth advocates the use of sterilized substrates, minimal egg movement, and the use of a different range of temperatures for reptiles from temperate and tropical regions. In the final chapter

(Chapter Twelve), Deeming overviews details of the previous eleven chapters. What becomes apparent is that current knowledge about both the eggs and nesting environments of reptiles is still poorly known. This is, in part, no doubt the result of the phylogenetic diversity, the range of reproductive modes exhibited and the range of habitats occupied, both within and among extant reptile groups, and because much of this research has focussed on a few key species from each group. In closing, Deeming makes various suggestions for future research.

In summary, Deeming has done a fine job in assembling the extensive range of contributors and researchers that have participated in this book. All chapters are thoroughly researched and well referenced and the most recent publications and many unpublished data have been incorporated. It is refreshing to observe that the Squamata have been afforded additional space, which likely reflects the increasing amount of research conducted on this group. Nonetheless, while there is some overlap among most chapters, which enables the reader to begin at any chapter, others may find the continued reintroduction of specific, key features somewhat redundant. The text is well complemented with numerous tables (33) and figures and black and white photographic plates (38), which are especially useful for some of the more theoretical chapters (e.g., Chapters 6 & 7). On the downside, there are many typographical errors throughout the text, with all chapters having at least one such obvious error. While this problem could have easily been avoided with more rigorous proofreading during the editing phase, it does little to detract from the breadth and quality of material presented. *Reptilian Incubation* promises to be a substantial addition to this field, and a worthy and helpful guide for students and researchers of herpetology and evolutionary ecology for years to come.

Many species and populations of amphibians are threatened, in severe decline, or have recently become extinct. With the problem at its zenith, concerned herpetologists and biologists around the world are trying to monitor populations, understand the reasons for such declines and extinctions, and provide possible solutions. National assessment of species at risk and the nature of the threats they face is an important step in this process. Amphibian richness in countries of tropical America is the highest in the world, but monitoring there has never been a priority, and thus information on amphibian populations is scarce and difficult to assess. *Libro Rojo de los Anfibios de Colombia*, published in the series Libros Rojos de Especies Amenazadas de Colombia, provides a comprehensive example for other countries to follow.

The book begins with two beautiful but small maps of the country, one political, the other physiographic. Following the table of contents, are prefaces by S. Suárez Pérez (Colombian Ministry of Environment, Housing and Territorial Development) and J. V. Rodríguez-Mahecha and F. Arjona (Conservation International, henceforth CI), acknowledgements, and a prologue by C. Gascon (CI). Colombia has the highest number of amphibian species (733) on Earth, making the task of the book a challenging one. The prologue emphasizes that the categorization of endangered amphibian species was a collective task that combined scarce quantitative data with the subjective interpretations of each specialist. The 24 contributors include specialists in each species or group of species and each taxon account is separately authored by one or more of these.

The Introduction is divided into several sections. "Generalidades de Colombia" includes geographic and hydrographic background and a very short explanation of Colombia's biogeography. I think that a more extensive introduction would have been more appropriate in order to place Colombia's high biodiversity (estimated to be 10% of the world total), in the context of the complex geography of Colombia.

Next a brief resumé of the history of herpetology in Colombia leads into an introduction of the general problem of endangered amphibians and the principal threats they face, like the destruction of natural habitats (e.g., only 1,200 km? or the original 80,000 km ? of deciduous and semi-deciduous forests of Colombia remain and only 27% of the original Andean forests persist). Other threats that amphibians confront are the fragmentation of habitats, the introduction of exotic species (e.g., pines, eucalyptus, fishes, and the bullfrog, *Rana catesbeiana*), pollution from herbicides, pesticides and acid rain, an increase in UV radiation and broader issues of climatic change, and overexploitation due to scientific collection and the pet trade. Another subchapter deals with recent amphibian declines, mentioning fungal infection and synergistic anthropogenic factors, and another discusses priority areas for amphibian conservation. Here the authors state the necessity to select such areas on the basis of their concentration of unique threatened species, but recognize that efforts to protect endangered amphibians are limited by the economic capacity to conserve them. The next subchapter is about the conservation *in situ*, and how existing protected areas can help. "Initiatives for Colombian amphibian conservation" deals with strategies such as, the modification of local cultivation practices (like coffee, which is highly destructive!) and promotion of corridors between protected areas. Another section of the introduction deals with the ecogeography of endangered species, showing that only seven of the 55 endangered species in this book occur below 1000 m, whereas 42 are from Andean forests, from which about 350 species are known. Finally, the methodology employed in assessing the species is provided along with a very useful explanation of the IUCN categories, and procedures for their application.

This is not a scientific book, but rather an identification guide for not only specialists, but government functionaries, naturalists, and those who are not very close to the amphibian world, but are interested in combating amphibian decline. This wide use is facilitated by a section explaining how to use the book, with an illustrated dichotomous key. Five color plates follow with small illustrations and photographs of the species mentioned. The illustrations are exactly the same as those appearing later in the species accounts, and do not follow the established systematic order for amphibians (e.g., Duellman 1993; Frost 1985, 2004). This arrangement is confusing; for example, in one plate salamanders are combined with several *Eleutherodactylus*, one *Osornophryne,* and one *Atelopus*, and in the next they are accompanied by *Phrynopus*, *Eleutherodactylus*, *Gastrotheca*, *Hyla*, and *Rhamphophryne*). Some order should have been followed, if not systematic at least one based on UICN categories. Regardless, as all these pictures are also presented in the species accounts, their inclusion here seems redundant. Before the species accounts, a list of species per threat categories is presented, but this includes only 48 species, not the full 55 treated in the accounts.

The first accounts are about the Critically Endangered (CR) species. For each account there is an illustration or photograph, all of good to very good quality, a common name, the scientific name, the family, and the category. This is followed by taxonomic comments (when considered important), the etymology of the scientific name, a description (which is really a short definition), the distribution (with a local map containing the known distribution at the end of each account), habitat, natural history, current status and threats. Under the last heading the most recent year of observation, conservation measures taken (if any), and the conservation measures proposed are provided. An additional helpful bit of information that could be included here in a future edition would be the number of specimens of each species in collections.

The last part of the book has a glossary of technical terms, followed by the acronyms used in the book, a literature section, and an index of common and scientific names. A map of the national parks of Colombia ends the book.

In general, I am happy to see this first step to do something about endangered amphibians in a neighboring country (I live in Venezuela), which is the first of its kind in Latin America. It is an attractive, well illustrated book, with a great deal of information on the general topics of amphibian decline and conservation and on the specific problems in Colombia. It meets all expectations for this first step by the authors.

One of the handicaps this book has is language, because it is written in Spanish. However, I think that all interested herpetologists working with tropical American species should be able to handle Spanish, at least to a reading level. I do, however, want to note some minor faults or details that could be improved in a subsequent edition. On page 76, in the section "How to use this book," a drawing of the dorsum of a frog appears, with some external anatomical features indicated. Two of these, "cloaca" and "glándula parotoidea" (parotoid gland) are not well delimited (especially the latter, because the frog is an *Eleutherodactylus*, which lack such glands!), and a non-frog specialist could be confused.

In the key (p. 81), couplet 3 leading to frog families says "palmeaduras sólo en las patas" (webs only on the feet) and is applied to dendrobatids and leptodactylids, although there are some dendrobatids with reduced webs and many *Eleutherodactylus* have no webs between the toes. On page 92, pictures of what I recognize as *Bufo granulosus* as an example of granular or tubercular skin, and the skin of *Atelopus farci* demonstrating a skin with warts, are not very adequate for the leptodactylids (mostly *Eleutherodactylus*). Likewise, illustrations (p. 93) of *Eleutherodactylus mnionaetes* dorsal skin as having "pliegues dorsolaterales cortos no extendidos" (dorsolateral folds short and not extended), and *Dendrobates lehmani* as illustrating "piel del dorso con tubérculos o gránulos bajos" (dorsal skin with low warts) are not the best examples to use (*D. lehmani* has completely smooth skin!). On page 96 there is a mention of "ranas grandes, LRC superior a 35 mm" (big frogs, SVL superior to 35 mm), and on page 98 the text reads "[ranas de] tamaño mediano, LRC= 56 mm)" (medium sized frogs, SVL = 56 mm). Although a specialist should understand that a dendrobatid of >35 mm can be considered big, and that an hylid of 56 mm can be considered of medium size, this is again confusing for non-specialists. Also, some terminology employed in the key, like "cabeza en forma de casco" (casque-headed form) for *Gastrotheca*, may have little meaning for non specialists. Even I do not find any similarity between a casque and

the head of a *Gastrotheca*.

In the current status and threats section of the *Atelopus ebenoides*, it is stated that *A. e. marinkellei* was last seen in 1995, but this information is not provided for *A. e. ebenoides*. In the same account the authors state that the species decline is related to global warming. Although all herpetologists are sure that global warming has a lot to do with the decline of some species, there is no direct evidence of such a link for this particular species.

The etymology of *Atopophrynus syntomopus* is not complete (the meaning of the generic name is not explained). That for *Atelopus subornatus* is inaccurate; the epithet makes reference to the fact that the species is ornately patterned on the underparts, not specifically that they are red or orange below. No meaning is given for the meaning of the specific epithet of *Atelopus farci*, although Lynch (1993) clearly stated that the nominative was "the acronym for a guerrilla group in Colombia (FARC) that frequents forests (especially cloud forests) and is dressed in khaki. Although FARC disrupt Colombian society, it does provide protection to the endangered cloud forests and their non-human inhabitants. The species is dedicated to FARC for its conservation, but not political, efforts." Indeed, it is strange that the armed conflict between the national army, the two main guerrilla groups (FARC and ELN), and the paramilitaries, which has catastrophic consequences for nature in general (e.g., deforestation, coca cultivation, use of herbicides) is hardly mentioned in the text at all.

Several illustrations are reproduced from other sources without attribution. For example, drawings of *Cryptobatrachus nicefori* (p. 160) from Cochran and Goin (1970) appear without citation, and in *Atelopus minutulus* account (p. 191) an unreferenced drawing of *Atelopus* sp. eggs comes from Lynch (1986). Illustrations of two types of *Atelopus* (*ignescens* and *longirostris* groups; p. 196), also unattributed, are derived from Peters (1973). References for illustrations are also lacking for should appear in pages 285, 290, 294, 320, 324 and 363, for *Phrynopus adenobrachius* (p. 285), *Rhamphophryne rostrata* (p. 290), *R. truebae* (p. 294), *Eleutherodactylus carranguerorum* (p. 320), *E. fallax* (p. 324), and *Rhamphophryne macrorhina* (p. 363).

In the account for *Colostethus edwarsi*, the description uses the webbing formula of Savage and Heyer (1967), although it cites Heyer (1967). Anyway, I do not understand why this old formula is used when an improved version was provided by Myers and Duellman (1982) and more recently by the original authors (Savage and Heyer 1997).

In the taxonomic comments for *Eleutherodactylus lichenoides* (p. 231), the author (Lynch) states that there are almost 200 species in the *E. unistrigatus* group, when on page 260, other authors (Rueda-Martínez and Rueda-Almonacid) say that there are about 150 species in the group. This is especially strange given that Lynch and Rueda-Almonacid have collaborated in many descriptions of *Eleutherodactylus*. Elsewhere it is stated that the lowland frogs of the *Atelopus longirostris* are not referred to in the book, but in fact *A. minutulus*, which has a species account, is referable to this group.

On page 276 photos two species of *Gastrotheca* appear, but these are not identified. The same is true of two species of *Dendrobates* appearing on page 306. A series of photos showing individual variation appears in the account of *Dendrobates occultator* (p. 311), but to me the species shown actually appears to be *D. bombetes*.

Finally, I will comment on the common Spanish names given to taxa in the *Libro Rojo*. Although it is perhaps odd to assign such names to species that are referred to only by specialists using their scientific names, it may be necessary for official purposes. I dealt with a similar issue in my list of Venezuelan amphibians (Barrio-Amorós 1998). While many names coined here make sense, others seem less appropriate. For example "rana saltona" (jumping frog) is given for *Colostethus*, which are usually called rocket frogs, and the "salamandra corpulenta café" (coffee robust salamander) for *Bolitoglossa lozanoi* seems less useful than "salamandra de Lozano." "Rana de lluvia de ojos rojos y amarillos" (red and yellow eyed rain frog) is provided as a common name for *Eleutherodactylus actinolaimus*, which has neither red nor yellow eyes! This might be better called "rana de lluvia de gola rayada" (throat striped rain frog). Perhaps strangest of all is "rana ladrona de azúcar" (sugar burglar frog), a strange name that makes no sense, applied to *Eleutherodactylus phragmipleuron*, for which something like "rana de lluvia [almost all *Eleutherodactylus* are called rain frogs] de Medellin" would have been more appropriate.

Despite my criticisms, I consider all these issues easy to solve in a future second edition of the *Libro Rojo*. This is a book of fundamental importance for all those who are concerned with amphibian declines, even if it is in Spanish (a good opportunity to learn a new language for some!), and a benchmark for all other countries in the Americas to aim for.

Acknowledgments.—I appreciate the comments of Ángela Suárez Mayorga on an earlier version of this book review.

In recent decades, lizards have become model organisms for studying general problems of ecology and evolution. Three previous international symposia on lizard ecology have resulted in proceedings volumes (most recently Vitt and Pianka 1994) that acquired a wide audience, both in and outside the herpetological community. *Lizard Social Behavior* is the proceedings volume of another related symposium organized by J. K. McCoy, S. F. Fox, and T. A. Baird at the 1999 Joint Meeting of Ichthyologists and Herpetologists. This symposium gathered investigators who use lizard models to address theory in sexual selection and the evolution of social behavior. Due to a general lack of parental care and other complicated forms of behavior, and because of their particular convenience for field studies, it is often more advantageous to use lizards to test some basic predictions about mate choice and sexual selection determinants than birds and mammals. This book has demonstrated this convincingly and it has already been favorably reviewed in a number of behavioral and ecological journals (Otter 2003; Staple 2003; Goodman 2005).

The book includes 11 chapters divided into three major sections according to the level of variation studied: variation among individuals within populations; variation among conspecific populations; variation between species. Each section is supplied with an introduction by an eminent behavioral ecologist (P. Marler, G. H. Orians, and G. W. Barlow) that summarizes the contributions and evaluates their methodology. The editors' general introduction outlines the advantages and special properties of lizard models.

Baird, Timanus, and Sloan (Chapter 1) monitored and experimentally manipulated social behavior in two isolated populations of the collared lizard *Crotaphytus collaris*. They present uniquely thorough data on seasonal, ontogenetic, and individual differences for both sexes and discuss their determinants, mainly in terms of costs and benefits of territory defense in various natural contexts. The next three chapters are mostly restricted to male behavior. Whiting, Nagy and Bateman (Chapter 2) provide an extensive overview of research on the evolution and maintenance of social-status-signaling badges in different animal groups and put in this context their study of the bright ventral coloration in *Platysaurus capensis* (Cordylidae). The badge size tends to reflect true fighting capacity; when experimentally increased, it enhances the contest success of its owner. Zamudio and Sinervo (Chapter 3) explore a peculiar polymorphism for male mating strategies found in *Uta stansburiana*. Three behavioral morphs – territorial owners, moderately territorial female guards, and non-territorial sneakers – which also differ in throat coloration, are genetically fixed, and this polymorphism is balanced by a frequency-dependent sexual selection. A great advance of this study is a reliable method of measuring reproductive success using a molecular genetic procedure. Cooper (Chapter 4) thoroughly reviews relationships between antipredatory behavior and social behavior in light of predictions of optimal escape theory. The author's field observations and clever experiments on the skink *Eumeces laticeps* coupled with related studies on some other lizards, demonstrate that males often need to trade off time spent avoiding predators with time spent engaging in courtship, mate guarding, and territory defense. Social and mating costs of autotomy were also considered in depth in this chapter.

The second section of the book includes investigations of conspecific populations in different environments. Using both field and experimental approaches, McCoy, Baird and Fox (Chapter 5) studied sexual size dimorphism, sexual dichromatism, and various parameters of social and mating behavior of both sexes in three Oklahoma populations of *Crotaphytus collaris* (cf. Chapter 1). The results conform to their hypothesis that the study environments differ in their potential for intra- and intersexual selection — the phenotypic outcome (dimorphism, behavior) being additionally affected by natural counter-selection which also varies in intensity among habitats.

The next two chapters consider variation among island populations. Hasegawa's long-term investigation (Chapter 6) on the skink *Eumeces okadae*, which inhabits the Izu Islands of Japan, reveals an unusual, positive association of predation rate and sexual selection intensity. Under greater predation, females show a highly secretive behavior that results in a strongly biased operational sex ratio and exerts the male-male competition for mating opportunities.

An extensive study of lava lizards (*Microlophus* spp.) from the Galápagos Islands by Stone, Snell, and Snell (Chapter 7) addresses possible effects of the rates of predation, parasite infection, and food supply (these vary as predicted by island biogeography) on lizard population density, behavior, and morphology. The results suggest the importance of predation in shaping the inter-island variation in body size and shape, population density, and social system.

The final section addresses the variation between species; its contributions vary substantially in their research design and approach. Hews and Quinn (Chapter 8) explore the endocrine basis of signal coloration and behavior in a range of *Sceloporus* and *Urosaurus* species. Some of the species are dimorphic, with males differing from females in having a colorful patch and more aggressive behavior; the other species are not dimorphic, both sexes exhibiting either masculine or feminine pattern of the first group. Interspecific and sexual differences in target-tissue receptivity

(rather than hormone level) were identified as the primary proximate determinant for the observed diversity.

Gier (Chapter 9) compares two iguanid species, *Ctenosaura similes* and *Dipsosaurus dorsalis*, which occupy vastly different habitats (forest and desert), to reveal environmental correlates for the differences in their mating systems and sexual size dimorphism.

Fox and Shipman (Chapter 10) studied seven closely related *Liolaemus* species occupying different elevations in central Chile. Local environment was a more important determinant of social behavior than phylogeny. In this system, the highest study site (2900 m a.s.l.) provides the most optimal habitat (better thermal opportunities and food supply, low predation rate). The highland species, *L. bellii* and *L. leopardinus*, are more abundant and less aggressive than the other forms; also, they are more interactive, suggesting a more complex social behavior that has rarely been reported for other lizards (e.g., O'Connor and Shine 2003). This study uses original methods to quantify lizard thermal opportunities and to factor out phylogenetic effects.

The final chapter (Losos, Butler, and Schoener) discusses aspects of sexual dimorphism in body size and shape in the Caribbean anoles, whose repeated radiation on different islands produced the same set of ecomorphs adapted to particular habitats. The study offers further evidence that (1) local conditions, rather than phylogeny, determine patterns of sexual dimorphism in external morphology, and (2) habitat types can differ in their potential for sexual selection.

Each chapter clearly outlines its hypotheses and how they were tested. Extensive reviews of relevant literature include both special and more general contexts, and the pooled reference list (pp. 381–434) is valuable *per se*. This makes the book useful for both experienced researchers and students.

My minor criticism concerns an editing issue. In a number of places (particularly Chapter 5) the book contains sentences or larger text blocks that seem unnecessarily complicated, including apparent redundancies or other faults.

Overall, *Lizard Social Behavior* is an outstanding contribution to reptilian behavioral ecology, a must-have for everybody from this field and those who are dealing with sexual dimorphism and sexual selection. This book is also of great interest for students of life-history, ecological morphology, and particularly for evolutionists. Indeed, it may well have been appropriate for the book to have been entitled *Lizard Social Behavior: Evolutionary Implications.*

Fifteen years have elapsed since 'amphibian' and 'decline' first became welded together in our imaginations. Prior to the recognition of decline phenomena, amphibian conservation was a sleepy corner of our science. A Web of Science query (conducted 10 October 2005) reveals that of 392 articles answering to a subject search for 'amphibian and conservation' just one was published prior to 1990. During the ensuing explosion in research we have learned our initial suspicions were largely correct: the problem of declining amphibian species is widespread and severe enough to lead to multiple species extinctions in some regions (Houlahan et al. 2000; Stuart et al. 2004). Early on there were some, particularly in the media, who sought to characterize declines as emanating from a single mystery cause. Many biologists argued back that there was not enough known to decide what factors were responsible. While we still may claim ignorance, anyone concerned about the issue can now heft the 1100+ page volume entitled *Amphibian Declines: The Conservation Status of United States Species*, edited by Michael Lannoo.

The proportions of this book offer the first important clue about its contents. Lannoo has adopted an 'all flowers shall bloom' approach to amphibian declines. There are no fewer than 215 contributors; there is a decent chance you are one of them. So let me begin by noting that the book offers a definitive look at the issue of amphibian declines. While the stated geographic scope is the United States, several of the authors work elsewhere in the world. Issues which might not be expected to get top billing in a book on the U.S. are dutifully covered as are essays (52 in total) on every other potential cause of declines you may have heard of. In fact, it would be extremely difficult to fault the book for topics it fails to touch on. If amphibian declines are important to you, and they should be, then you should read this book.

But what does it mean to read a book like this? This was the first question crossing my mind as I attempted, unsuccessfully, to fit the new volume in my bookbag. Lannoo states that his intent is to "assemble and integrate" what we know about declines. A quick scan of the table of contents suggests this process has not incorpo-

rated meaningful triage. That job has been left to readers who must decide why, for example, there is an entire chapter on renal adenocarcinoma. If you were wondering whether there is any evidence to link this cancer to declines, the authors helpfully put that concern to rest: "…there appears to be little about the Lucké renal adenocarcinoma to concern population biologists (p. 101)." Other chapters focus on limb malformations. One can argue the case for inclusion: we still don't know whether abnormal limb development is a threat to amphibian populations. But why are there two of them and by what criteria is an additional chapter on the basic biology of trematodes justified (Trematode parasites *may* be responsible for some limb deformity outbreaks in nature and limb deformities *may* cause declines)? Chapters with dubious claims on the attentions of readers interested in declines are numerous. Fortunately, there are also outstanding, topical essays that will leave readers informed and intrigued.

The many essays offering overviews of research areas (e.g., Ecotoxicology authored by Ray Semlitsch and Christine Bridges) offer brief, informative summaries that give an idea of what has happened and where the field is headed. Many are structured like primers and are likely to be most useful for the uninitiated. Other more targeted essays are likely to be more appealing to specialists. As one example, a series of three essays on the Cricket Frogs (*Acris crepitans*) of the upper Midwest leaves readers with a well developed picture of a regional decline. While the authors of these studies are still far from determining the cause for declines, they have been unusually thorough in their use of observational data in the development of their research. In the study of some other North American declines there has been a tendency to rush immediately to experimentation without clearly describing the phenomenon to be understood. While the observation first approach is not fast, it is far more likely to lead to robust inferences (Storfer 2003).

Other essays are less about science than its context. A well titled chapter on "Houston toads and Texas politics," authored by Lauren Brown and Ann Mesrobian, leads the reader through an agonizing series of events and decisions that provides a warning to be heeded by all involved in amphibian conservation. The Houston Toad (*Bufo houstonensis*), a federally listed species, has gotten the kind of protective status and public attention that many biologists can only dream of garnering for their imperiled species. Nevertheless, there is little evidence that this has helped the toads much. This essay shows in stark terms that while we continue to toil to raise public awareness and provide evidence of threat, we will do well to consider what will or won't happen next. This theme is echoed in an excellent essay written not by a biologist, but a journalist. William Souder argues that amphibian biologists have been largely ineffective in communicating their findings to the public and offers some reasons why. His sobering chapter makes it clear that some of the obstacles are inherent in the way the media covers science—amphibian biologists hoping to surpass these hurdles will do well to consider his counsel closely.

Close followers of the amphibian decline literature will know that the last few years have witnessed the publication of a great deal of important research. This fact makes it especially disappointing that many of the essays in a book with a 2005 publication date appear to be a few years old or older. Whether this delay is a byproduct of attempting such a large publishing project is not clear. Regardless of its origin, the effect for readers is unfortunate. While it remains true that many of the essays still offer the most recent treatment of their respective topics, several have been superceded; for the remainder, readers will be left wondering how they might have changed given consideration of more recent work.

Another critical aspect of the book is tipped by its title. *Amphibian Declines: The Conservation Status of United States Species* is actually two books in one. The second half of the book is comprised of species accounts focusing on "the conservation status of United States species." Each account is divided into four categories (Historical versus current distribution, Historical versus current abundance, Life history features, and Conservation). Within the life history section there are 18 subheadings covering everything from breeding mode to longevity to anti-predator mechanisms. Anyone familiar with the amphibian literature will not be surprised that for most of these categories we know next to nothing for many of the 289 species recognized. However, the accounts offer nice summaries of what we do know and even experts can expect to learn new information about their own study species.

These accounts will undoubtedly be enormously useful to people interested in amphibian conservation as well as basic researchers. However, I must admit believing that a tremendous opportunity remains. The authors of the accounts invoke classic volumes such as Wright and Wright (1949) as the inspiration for their national scale effort. However, in 2005 should reference information like this be distributed in a printed book when it is so much more suited for distribution via the Web? To answer this question for yourself, check out the British Trust for Ornithology's Birdfacts database (http://www.bto.org/birdfacts/) and compare it with this or any book attempting to relate comparable information. Many of the same categories appear in Birdfacts which also includes legible maps and figures that can be easily updated as new information appears. Even the underlying data can be made available to users who can then readily generate their own summaries and customized comparisons. With apologies to salamander biologists, a "Frogfacts" database based on Lannoo et al.'s efforts could offer a highly useful complement to existing sites relating information on amphibian population monitoring (http://www.pwrc.usgs.gov/naamp/) and malformations (http://frogweb.nbii.gov/narcam/).

While perhaps cumbersome in their present form, one great benefit of including the species accounts in the book is the opportunity to summarize what they tell us about the overall status of the U.S. amphibian fauna. David Bradford takes on this challenge in what is arguably the most important essay in the book. His chapter is full of information that is clearly presented and, possibly, more striking and important than the understated and businesslike delivery will suggest to many readers. In fact, it leaves a large elephant in the room.

Amphibian biologists have spent 15 years amassing and supporting various hypotheses without doing much to eliminate them. Bradford's review offers one of the few opportunities in the book to get an overview of what we have learned and to decide where to go next. He shows very clearly that just three decline mechanisms can be considered broadly relevant to U.S. species: land use, exotic species and chemical contaminants. Of these land use is far and away the most often cited. The essay relates this finding with very little comment, but comment it deserves. If those interested in conservation want to take on the most important threats to amphibian populations in the United States, the most comprehen-

sive, national scale consideration has a clear answer—and it will be surprising to many people.

These findings, presented at the end of the book, offer a nice bookend to Tim Halliday's opening chapter in which he notes that we have excellent evidence that there is no 'smoking gun,' if by smoking gun we mean a single cryptic cause. He argues that it is high time to follow a critical consideration of what we have learned with a refocusing of our efforts on the factors that do matter. This will mean deciding that some avenues of research deserve less attention. One of the most critical unspoken conclusions from Bradford's essay is that ultraviolet radiation can now be placed in such a category. UV was one of the first nominated causes for declines and has received more attention than perhaps any other hypothesis. Bradford's review suggests that as a threat to U.S. species, UV ranks along with harvest as a minor issue. Recent work, not cited here, has called the relevance of UV for declines into serious doubt even for those species and regions where it was initially studied (e.g., Biek et al. 2002; Palen et al. 2002). If amphibian biologists are serious about achieving conservation goals, Halliday cogently argues that we will have to shift some of our attention to understanding demography of amphibians in human affected landscapes and their reliance on connections between wetland and upland, and among populations.

In the early 1990's declining amphibian populations attracted the notice of biologists and the public in large part because there was a strong suspicion that something unusual was happening. In essay after essay the veterans of the research campaign report that it is quite likely that there is nothing unusual about many U.S. amphibian declines. Amphibians offer typical stories from the conservation front: a set of factors, predominantly related to human use and alteration of the environment, is acting to reduce and eliminate populations and species. Along the way, biologists have also shown that amphibians may need to yield their unique 'canary' status—several authors note that it is time to stop considering amphibians to be unusual or particularly sensitive to environmental insult. Curiously, in being typical, future studies of declining amphibians may be in an even better position to offer lessons for the conservation of other animals less amenable to study and for which a book of the size and thoroughness of "Amphibian Declines: The Conservation Status of United States Species" is unlikely to appear for a long time to come.

El Salvador (ES) is the smallest of the seven Central American countries and the only one located entirely on the Pacific versant. As such, its known herpetofauna of 130 species (32 amphibians and 98 reptiles) is also the lowest total for the seven nations. Nonetheless, a comprehensive synthesis of the ES herpetofauna was previously lacking (Mertens 1952, in his review of the ES herpetofauna, treated 23 amphibian and 75 reptilian species that were largely collected by German naturalists) and this book admirably fills that void.

The book begins with a short (1 p.) introduction followed by a two page materials and methods, each listed as a separate chapter. Chapter 3 (5 pp.) is on the environment and provides short descriptions of the country's physiography, climate, and vegetation. Chapter 3 also includes two maps, one showing the political boundaries of the country's departments and the other showing the country's "ecoregions." Ten plates showing various vegetation types accompany this chapter. Chapter 4 (4 pp.) is titled "Composition of the Herpetofauna" and includes a table on the taxonomic composition of the ES herpetofauna and another listing those taxa with a type locality in ES. A section on erroneous and questionable records is also included. Chapter 5 (64 pp.) treats the Class Amphibia and includes bilingual (English and Spanish) dichotomous keys to the adults of the three amphibian orders found in ES, the four salamander species, the 27 anuran species, and the larvae of 23 (counting both *Hypopachus barberi* and *H. variolosus*, which cannot be distinguished from one another morphologically) anuran species (not 20 as stated by the authors). Chapter 5 also includes the species accounts of the 32 amphibians known from the country. Each species account includes the scientific name (along with authorship), a suggested Spanish common name, a partial synonymy, geographic distribution (overall), ecological

distribution (in ES), description, call (anurans only), natural history, conservation status, and specimens examined (including precise locality records and museum numbers). Some of these species accounts also include a list of published locality records of specimens not examined by the authors, and occasional accounts also contain a section on taxonomic comments. Each species account also includes a color photograph of the animal and a map with the ES localities plotted. Drawings of some features of many of these species are also included. Drawings of the oral discs of 12 species of anuran larvae also complement the tadpole keys. Chapter 6 (141 pp.) treats the Class Reptilia. Bilingual dichotomous keys are also included for the "major groups" ("Serpentes, Testudines, Crocodylia, and Sauria"), the two crocodilian species, the eight turtle species, the 30 lizard species, and the 58 snake species. The reptile species accounts follow the same general format as those of the amphibians, except that the conservation status of most species is not given and the natural history sections are omitted from the *Drymobius chloroticus* and *Leptophis modestus* accounts. These reptile species accounts also include a color photograph of each species, a dot locality map for each species, and numerous drawings. Following Chapter 6 is a 16-page Literature Cited section that has 392 references listed (including several to web sites). The final section is a four page index that includes scientific names (species names listed by genus), higher rank names, and selected other names or words mentioned in the first three chapters.

The species descriptions are usually based on data taken from ES specimens, but occasionally information had to be taken from the literature (e.g., much of the sea turtle and crocodilian descriptions) or on data from specimens from other Central American countries or from southern Mexico (e.g., *Hyalinobatrachium fleischmanni*). These species descriptions necessarily vary in length, but I found them all to be well done. These descriptions used along with the identification keys should allow one to correctly identify any specimen of amphibian and reptile in hand from the country. The only complaint I have about the descriptions and identification keys is that there is no glossary to identify the numerous terms used. Given that the identification keys are not illustrated, it is even more desirable to have had a glossary included. Also, the meanings of ecomorphological guild (e.g., nektonic) and developmental mode (e.g., exotrophic) terms used for anuran larvae should have been explained in a glossary.

The natural history sections include information from the authors' field notes when available, field notes of others who have worked in the country, and published data from ES and other Central American countries. The information presented in this section nicely summarizes the available information on the natural history of each species. The call sections of each anuran species account also summarize what is known and point the interested reader to the pertinent literature.

I was especially pleased to see the detailed locality data and museum numbers for the voucher specimens included in the "Specimens examined" and "Published locality records" sections. Compiling these types of lists are very time consuming and tedious, but add greatly to the usefulness of these types of books. However, I would have liked for the authors to have included an accompanying gazetteer that gave the location, elevation, and coordinates for each locality. Also, the locality maps for each species account would have benefited from having the departmental boundaries identified. I also found one error in that the map of *Eleutherodactylus rupinius* has the open squares wrongly placed.

Putting together color photographs of 130 species of amphibians and reptiles is a time consuming and difficult task. This task was complicated by the authors' understandable desire to use photographs of ES specimens when possible. As a result, several of the used photographs are poorly focused or too dark. Two photographs that were used, indeed do demonstrate the desirability of using ES photographs when possible. The photograph of *Dryadophis* (= *Mastigodryas*) *melanolomus* used (from Nicaragua) shows a salmon colored venter, which color is restricted to populations from northeastern Honduras southward through Costa Rica, and that of the *Leptotyphlops goudotii* used (from the Islas de la Bahía, Honduras) shows a vividly striped pattern and large yellow snout and tail spots, whereas those from ES are typically essentially black with smaller snout and tail spots.

The drawings accompanying the species accounts are well done and add greatly to the overall appearance of the book. I found two errors with these drawings as follows: Figs. 9a = *Ptychohyla salvadorensis* and 9b = *P. euthysanota* instead of the opposite as stated in the figure legend; Fig. 41 shows the color pattern of a *Pliocercus elapoides* on a drawing of the head scales of a somewhat modified *Micrurus nigrocinctus* (compare with their Fig. 48a).

This book is remarkably free of typographical errors; I was able to find only Santa Lucia (= Santa Lucía) on Page 165, Tala (= Tela) on Page 210, and Ophidea (= Ophidia) twice on Page 219. Errors of other types also seem to be largely lacking. Three I found are: the reference Campbell (1989) on Page 12 is not included in the Literature Cited; the statement on Page 43 (Taxonomic comments), attributed to McCranie and Wilson (1999), that the prepollical width/prepollical length of the single male *Plectrohyla psiloderma* from ES falls within the range of *P. glandulosa* is erroneous; and the correct locality data for the *Rhinophrynus dorsalis* in Plate 42 is "HONDURAS: Yoro: Tegucigalpita (20 m)." I would also take exception to the statement on Page 82 that members of the family Cheloniidae are "Closely related to the leatherback turtle (Dermochelydidae)."

The layout of this book is attractive with the photographs and species maps placed nicely within the species accounts. The text is not right-hand-justified, which is unusual among herpetological books, but does not detract from the overall appearance of the book.

Despite my minor criticisms, the authors have combined their knowledge of the ES herpetofauna to produce a very useful and detailed book on the herpetofauna of that Central American country. The authors certainly succeeded in summarizing the morphological variation and distribution of the amphibians and reptiles of ES as they stated was their goal in their Introduction. Anyone with an interest in the natural history of Central America should own a copy of this book.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.html>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution or Natural History notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information below) or from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Dr. Theodora Pinou, SSAR Treasurer, Western Connecticut State University, Department of Biological & Environmental Sciences, 181 White Street, Danbury, Connecticut 06810, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below), regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 760	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com.

HERPETOLOGICAL HUSBANDRY

plicable to other elements of pattern. Future advances in technology (i.e., ambystomatid pattern-recognition software, Ravela and Gamble 2004; D. Church, pers. comm.) will automate the process of identifying individuals. Pattern recognition research is progressing in the field of facial recognition (Zhao et al. 2000), and this emerging body of literature (and associated products) can have practical applications for wildlife biology. Even with automated pattern recognition, a subset of computer-determined individuals may require validation using methods similar to the process we present (see also Whitehead 1990; whale fluke identification). Regardless of method, some assessment of bias is useful in evaluating whether a technique violates the assumptions of capture-recapture modeling (specifically 1) that marks are not lost during the period of study and 2) observers can recognize marked individuals, and do not designate marked individuals as new captures). Validation of data subsets can allow investigators to evaluate a marking approach, and thereby qualify the derived estimates of population size or trend.

Acknowledgments.—This project was supported by the USGS Amphibian Research and Monitoring Initiative, Northeast region. Brand names provided in this paper are for information only and do not constitute endorsement by the US Geological Survey. Our manuscript was greatly improved by comments from L. Bailey, S. Doody, L. Gamble, M. Mazerolle, D. Olson, C. Phillips, and two anonymous reviewers. Many thanks to the observers including R. E. Jung, A. Mongeon, T. Plenderleith, and E. Wilson. We also thank W. Crouch for insightful discussions, L. Bailey for suggestions on study design and data analysis, and the late Laura Mazanti for initiating the study of Spotted Salamanders at this study site.

Further Observations of Oviposition in the Surinam Toad (*Pipa pipa*), with Comments on Biology, Misconceptions, and Husbandry

KEVIN C. ZIPPEL
IUCN/SSC Conservation Breeding Specialist Group
25 Spring Street, Union Springs, New York 13160, USA
e-mail: zippelk@yahoo.com

Although the Surinam Toad (*Pipa pipa*) was originally described in 1758 (as *Rana pipa* by Linnaeus), published information on the biology of this species has been slow to accumulate. The limited information available has been derived largely from preserved materials and observations of a few captive specimens. This note reviews the biology of the species, details original observations on reproductive behavior in captivity, aims to dispel some persistent misconceptions, and offers recommendations for captive husbandry in the interest of stimulating further research.

The Surinam Toad occurs widely throughout northern South America and is certainly one of the strangest and most fascinating of all anurans. From its morphology to its reproductive mode, this species is strikingly different from what we think of as "typically anuran." *Pipa pipa* is extremely depressed (dorso-ventrally flattened) and has a broad, triangular head with several fleshy sensory protuberances, a huge mouth, and tube-like nostrils. These traits combine to produce a bizarre appearance uncannily similar to that of the Mata Mata Turtle, as noted by Rabb (1969) and Armburst (1979). At 10–20 cm body length, their size is equally

impressive. Although the common name 'toad' suggests otherwise, pipids in general are primarily aquatic frogs that rarely venture out of water. However, they have been observed moving over land in the wild (Buchacher 1993; Deuchar 1974; Hewitt and Power 1913; Myers and Carvalho 1945; Pefaur and Cardoso 1992; Pough et al. 1998; Wager 1965; Zippel, pers. obs.) and will readily leave open-top aquaria.

Pipids tend to inhabit murky or swampy water where their vision is likely obscured and they rely on tactile cues delivered through the sensitive protuberances on their face and fingertips and through their lateral-line systems. Schüette and Ehrl (1987) discussed in detail the structure and function of the fingertips as tactile organs. The eyes of *Pipa pipa* are very small and anterolaterally placed (see misconception #7 below regarding their ability to see). Rabb (1969) offered that wild Surinam Toads are known to eat "crayfish and small spiny catfish;" Duellman (1978) found two relatively large fish—"an *Erythrinus erythrinus* (Erythrinidae) 30mm long and a somewhat smaller pimelodid catfish"—in the stomach of a wild 78 mm Surinam Toad. Captives will eat almost any appropriately-sized animal or piece thereof (see husbandry recommendations below). Their small forearms seem to move in a single plane, from in front of the face to the open mouth. They execute this movement repeatedly as they sift through benthic debris looking for food. The hind legs are large and powerful with heavily webbed feet and are used for propulsive swimming. The hind foot even has a spade, similar to that in *Scaphiopus*, which might be used for burrowing into loose benthic substrate.

Male Surinam Toads might be slightly smaller than females and have thicker forearms. Males have a pointed, down-turned cloaca; in females, the cloaca is thicker, rounder, and upturned (Schüette and Ehrl 1987). The female cloaca in swollen, reproductive condition is illustrated in Rabb and Snedigar (1960) and clearly photographed in Armburst (1979), Rabb (1961), Schüette and Ehrl (1987), and Shibuya (1968) (see misconception #3, below). Males call year-round, particularly at night, but with greater frequency and intensity in the breeding season, which might be annual (Palmer 1994) or semi-annual (Schüette and Ehrl 1987). The call is produced by the striking of two small bones in the larynx (Rabb 1960). Single clicks are thought to be a challenging territorial call, while the more rapid series of clicks is probably a mating call (Rabb and Rabb 1963a). Schüette and Ehrl (1987) provided sonogram and frequency data. Males can be extremely territorial, and male-male combat involves head butting, grappling, biting, snapping, swooping, and kicking (Rabb and Rabb 1963a).

Breeding Behavior.—Certainly one of the more interesting and scrutinized aspects of *Pipa* biology is the bizarre behavior involved in reproduction. Amplexus is inguinal and can last for several days before oviposition. In all seven species of *Pipa*, the maneuvers involved in amplexus result in the eggs being deposited on the dorsum of the female. Here they are engulfed by the hypertrophying, tumescent integument and are incubated for periods of weeks to nearly half a year, depending on the species. In *P. carvalhoi* (Brazil), *P. myersi* (eastern Panama), and *P. parva* (northeastern Colombia and northwestern Venezuela), the eggs develop into tadpoles, which are released into the water after 3–4 weeks and filter feed until they metamorphose into aquatic froglets 2–3 months later. In *P. arrabali* (Guyana, Surinam, eastern Venezuela, and northern and central Brazil), *P. aspera* (Surinam), *P. pipa* (Colombia, Venezuela, Guyana, Surinam, French Guiana, Ecuador, Peru, Bolivia, Brazil), and *P. snethlageae* (Brazil), the eggs develop directly into froglets before being released into the water after gestation of two to nearly five months (Table 1).

That the eggs are brooded within the dorsum of the female Surinam Toad has been known since 1705 (Merian, *fide* Schüette and Ehrl 1987); however, it was not until a series of captive breedings at the Brookfield Zoo in the late 1950s and early 1960s that it was revealed how the eggs got there (Rabb 1961; Rabb and Rabb 1960, 1963a; Rabb and Snedigar 1960). Although this species has been bred at other zoos and by private individuals, observations and data are rarely published. Several other institutions or individuals, in Germany (Armburst 1979; Jahn 1982; Schüette and Ehrl 1987), Japan (Iwasawa 1979; Iwasawa and Tanaka 1980, 1993, 1994; Shibuya 1978), England (Bartlett 1896; Sclater 1895) and the US (Drewes 1977; Tenny 2002), have published articles regarding reproduction in *Pipa pipa*. Summaries of oviposition and gestation data (Table 1) and growth and development data (Table 2) are provided herein.

I was fortunate enough to observe a single successful breeding event, which is herein compared to the three documented breeding events (all involving a single female, two with the same male) at the Brookfield Zoo. All reproductive behaviors occurred as documented by Rabb and colleagues with one exception: the amplectant pair observed by me used a modified form of the ovipositional "turnover." According to Rabb and Rabb (1960, 1963a), the ovipositional turnover consists of two distinct rotations, one about the longitudinal axis (an ascending sideways half-roll) resulting in an inverted or upside-down position *near the water surface*, followed by one about the transverse axis (a descending head-first half-roll) returning the pair to an upright position on the substrate (Fig. 1A). Note: It is not a simple, circular somersault (see misconception #1 below). By my observations, the turnover sequence began with the amplectant pair at rest on the tank floor. As previously documented, the female pushed off sideways with a hind foot to begin the rotation about the longitudinal axis. However, the pair immediately flipped into the upside down position about 10 cm from the bottom, not near the water surface. From here, they swam backwards using jerky motions of the hind limbs and moved upwards into a vertical head-down position; it was during this movement that the eggs were released and rolled forward on the dorsum of the female. From the vertical position, the turnover was completed normally, and concluded with the typical tilted, resting position (Fig. 2).

The significance of this modification is unclear. It is not a function of water depth, i.e., that this pair had less vertical water space than the animals at Brookfield, and the initial longitudinal rotation left them too near the substrate to complete the transverse rotation. The Brookfield enclosure was actually shallower (see comments below in misconception #2 regarding water depth required for breeding). The frogs observed by me had 40 cm of vertical water available, but utilized only the lower 20 cm. Alternatively, this modified behavior pattern might represent variation among females: all three breedings at Brookfield forming the basis of the original descriptions involved the same female, two with the same male (Rabb and Rabb 1963a). In other documented breedings where turnover behavior was actually observed, variations similar to what I observed have been depicted or described. Ac-

[1] - the difference between # eggs oviposited and # implanted represents the lost infertile eggs and a few lost fertile eggs; infertile eggs might become attached prior to falling off, but are not implanted as are most fertile eggs.
[2] - gestation values include only animals that survived, omitting premature births.
[3] - nine of these died within the first month.

cording to the photographs in Shibuya (1978), the pair made their initial rotation about the longitudinal axis immediately, as did the animals I observed, such that they were upside down just above the substrate, not at or near the water surface. Armburst (1979) used the words "Salti rückwärts" or backward somersault to describe the maneuver, suggesting a backward-moving component to the ovipositional turnover. Translated from German: "A backwards somersault brought the animals into a nearly vertical position, head down." He also offered that the eggs were always released when the pair was in the vertical head-down position. His Figure 3 clearly shows the animals in a head down position perpendicular to the substrate and the legend reiterates that this is when oviposition occurs. As with my observations, there is a backward moving component to the maneuver, and eggs were laid during the vertical head-down component. Iwasawa and Tanaka (1994) also observed that oviposition occurred after the pair rotated transversely "when they reached mid-water rather than near the water surface ..." Sughrue (1969) showed a pair from the Brookfield breedings inverted just over the substrate, a position that likely would not allow a transverse roll without first some backward or

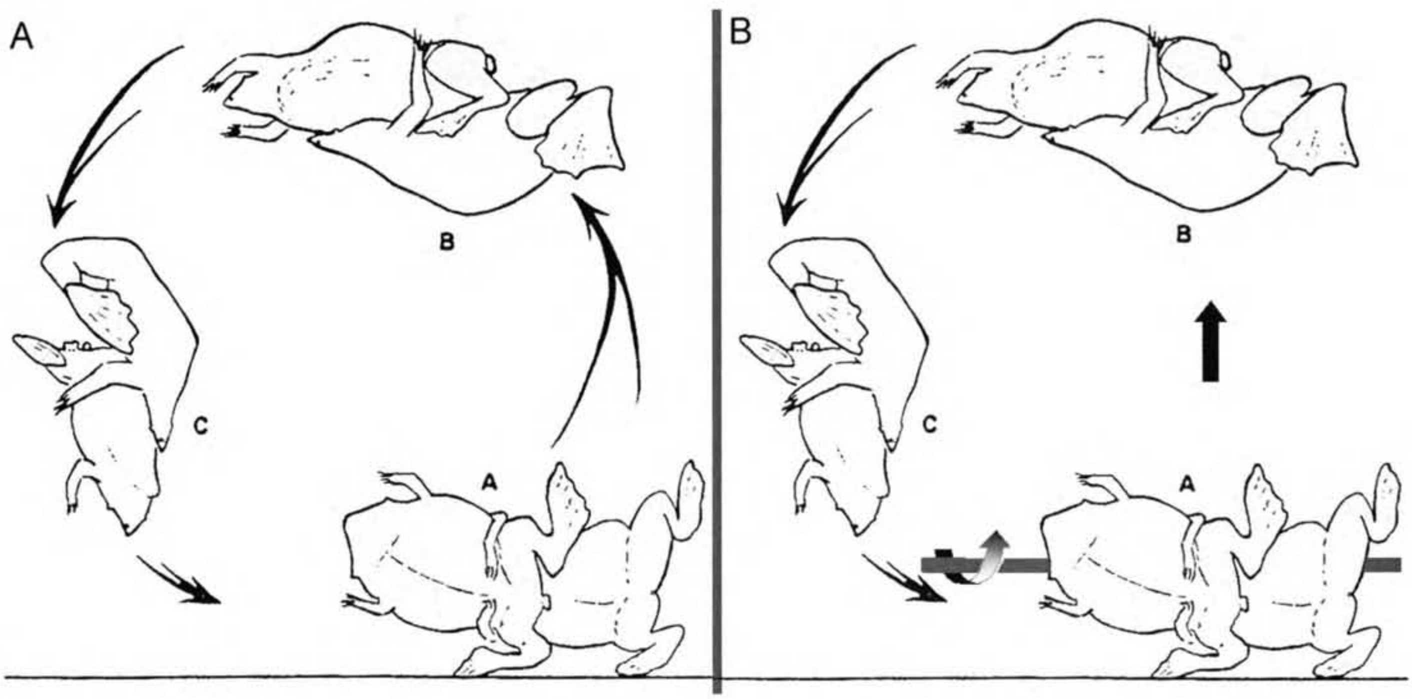

FIG. 1. The ovipositional turnover of *Pipa pipa* as observed by Rabb and colleagues. **A.** The original figure (Fig. 2) from Rabb and Rabb (1960), which might be misleading in its use of arrows connecting the different phases of the turnover using a circular format. **B.** My re-interpretation of the original: Position A has been moved directly under Position B and a straight vertical arrow connects the two. Note also the gray horizontal bar, which represents the longitudinal axis of the amplectant pair, the axis around which the first rotation occurs.

upward-moving movement. Eventually, Rabb (1973) changed his language, describing the location of the upside-down position and oviposition as "mid-water" without further explanation.

It is clear that the ovipositional acrobatics of *Pipa pipa* are more variable than is commonly assumed and are not clearly understood. Repeated observations, under captive conditions or preferably in the species' natural habitat, are required to determine the "normal" sequence.

Misconceptions.—In addition to my observations suggesting an element of variety in *Pipa pipa* ovipositional behavior, there are seven misconceptions that I wish to help dispel. Although several of these have been previously addressed throughout a disparate set of literature, some authors continue to miss them. These clarifications are herein summarized in one document, in the hope that the myths are not perpetuated in future works.

1. According to Rabb and Rabb (1960, 1963a), the ovipositional turnover consists of two distinct rotations: one about the longitudinal axis (a sideways ascending half-roll) leading to momentary pause in an inverted or upside-down position near the water surface, followed by one about the transverse axis (a descending head-first half-roll) returning the pair to an upright position on the substrate (Fig. 1). It can also sometimes include a backwards-swimming component during oviposition whereby the pair remains near the substrate (see discussion above, and Fig. 2). *In either case, it is not a simple, circular somersault.* This complex maneuver is photographed in Rabb (1961, unfortunately plates are printed in reverse order, per Rabb and Rabb 1963a,b), Shibuya (1978), and Sughrue (1969). However, it is still often described and illustrated as a circular somersault, both in the hobbyist/popular (Drewes 1977; Jahn 1982; Mattison 1991; Staniszewski 1995; Walls 1995; Zimmerman 1995) and academic secondary (Halliday and Adler 2002; Stebbins and Cohen 1995; Zug 1993) literature. This might be the result of misinterpretation of the Fig. 2 illustration in Rabb and Rabb (1960), recreated here in Figure 1A, which uses a circular format to show the different phases of the maneuver connected by arrows, thereby giving the misleading impression of a complete circular motion. I believe Rabb himself must have realized the confusion created; a later publication of this figure (1973) replaced the semi-circular arrow between A and B with a wavy arrow more vertical in orientation. I believe these figures would be

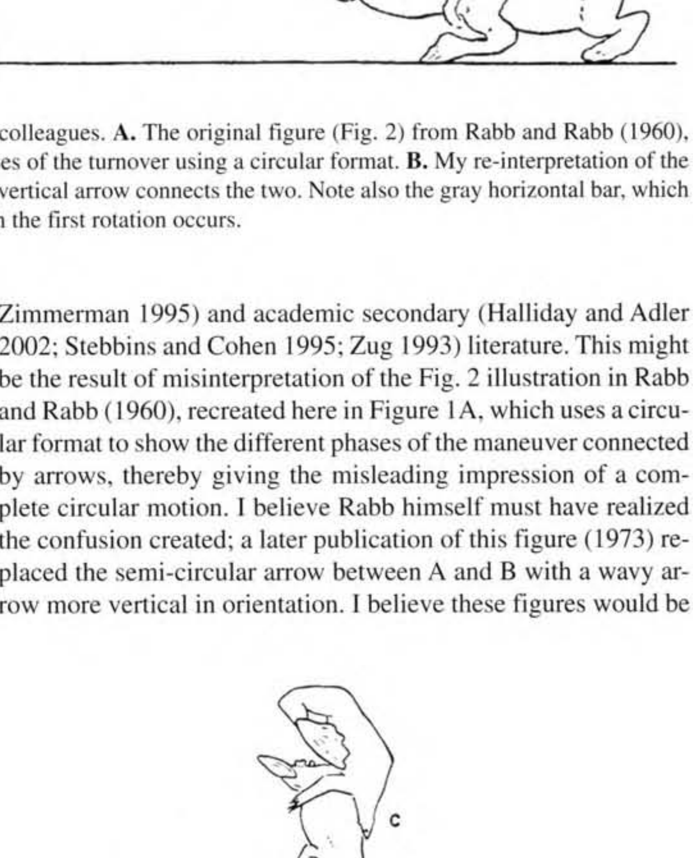

FIG. 2. The ovipositional turnover as observed by KCZ. Note that Position A has been omitted from this figure as it occurs largely in the same space as, and would be obscured by, Position B. That Position A occurs is assumed in this case; it would appear exactly as it does in Fig. 1. Oviposition occurs during the jerky backward movements transitioning Position B to C.

a more accurate reflection of Rabb's text if they used a truly vertical arrow to transition from Position A (on the substrate) to Position B (inverted) and had Position B directly above Position A. Thus, the movements include a longitudinal rotation during a direct vertical ascent, and a transverse rotation during a semicircular descent (Fig. 1B). Such a non-circular ovipositional maneuver occurs in other species of *Pipa* (Plunk 1996; Weygoldt 1976) and in some, but not all, non-pipine pipids (Rabb 1973; Salthe and Mecham 1974).

2. As a result of the circular somersault misconception, some authors have suggested that Surinam Toads require deep water for breeding to complete the "full circle" (e.g., Armburst 1979; Palmer 1994, Tenny 2002). Tenny recommended nearly 1 m of vertical water depth to allow for the ovipositional maneuvers; Palmer (1994) offered that anything less than 107 cm would result in failure of fertilization and implantation. This notion of required depth is also not uncommon in the zoo community. However, few of the successful breedings have had such depth available; in fact, most took place in surprisingly shallow water, not even twice the SVL of the adults. The original Brookfield breedings took place in a 70-liter tank (comparable to the industry-standard 20-gallon) (Rabb and Rabb 1960) and 28 cm of water depth (Rabb and Snedigar 1960). Drewes (1977) used a standard 15-gallon aquarium. The Toronto Zoo used a 150-liter tank with 25-cm deep water (B. Johnson, pers. com). Iwasawa and Tanaka (1993, 1994) offered 35 cm of vertical water. Armburst (1979), Schüette and Ehrl (1987), and the Denver Zoo (R. Haeffner, pers. com.) provided access to as much as 50 cm, while Palmer (1994) apparently offered ~120 cm. However, no other author described how much of the water column was actually utilized by the amplectant pair during breeding. I presented them 40 cm of water, of which they utilized only the lower 20 for their nuptial acrobatics. Palmer (1994) claimed annual success for 12 continuous years as a direct result of offering deeper water. He claimed that each ovipositional 'backflip' in deep water is accompanied by a close second backflip solely for fertilization, something which did not occur for him in shallow water. However, he offers no real data for comparison. This second fertilization maneuver has not been noted by anyone else working with *P. pipa*, other species of pipines (Plunk 1996; Weygoldt 1976), or other non-pipine pipids with nuptial acrobat-

TABLE 3. A summary of food items consumed by captive Surinam Toads (*Pipa pipa*). All whole-animal food items live unless otherwise noted.

Adults	Froglets	Reference

[1] - the author was relating this information from a colleague maintaining the *Pipa* in the field in Trinidad and speculated that these were *Leptodactylus* sp., further stating that fish were offered but refused.

ics (Rabb 1973; Salthe and Mecham 1974).

3. In several hobbyist articles and books, authors have referred to an 'extensible ovipositor' in the female (e.g., Staniszewski 1995). The source of this falsehood comes from the 1896 paper by Bartlett, in which he unknowingly describes a pathologic condition of prolapse in one ovipositing female that died shortly after breeding. Although female *Pipa* spp. in breeding condition do show a distinct swelling of the cloacal lips, to 4 cm diameter (Schüette and Ehrl 1987), there is no cloacal tube with which the male maneuvers the eggs onto the dorsum of the female. Rabb and Snedigar (1960) made this point offering an illustration of a normal swollen female cloaca, and Rabb and Rabb (1960) and Schüette and Ehrl (1987) reaffirmed it, yet the misinformation continues to persist.

4. The eggs are not received *into* a honeycomb-like structure on the back of the female, as is sometimes reported in the hobbyist literature (e.g., Staniszewski 1995). Rather, they roll between the venter of the male and the slightly swollen dorsum of the female, where they adhere beginning near the vent and advancing anteriorly. The skin then swells up around the eggs and they sink into it, *forming* the individual chambers. This process can take as few as two (Iwasawa and Tanaka 1994) or as many as 10 days (Rabb 1961).

5. The stroking behavior of the amplectant male has been the subject of some speculation. Rabb and Rabb (1960) observed this behavior 11 times near the end of oviposition, both before a turnover and after a trip to the surface for air. The male was reported to swing his hind leg forward alongside the female's back, as far forward as the back of her head, and this movement was interpreted as stretching or a mechanical stimulus for inducing oviposition. It was observed again late in a subsequent breeding, after the female had gone into a swimming frenzy when frightened by a camera flash, and re-interpreted as an expression of dissatisfaction on the part of the male (Rabb and Rabb 1963a). In Sughrue (1969), it was called "a stimulating gesture." It was later shown in male *P. carvalhoi* that the stroking movements of the male's hind feet facilitate egg adpression (Mattison 1993; Weygoldt 1976; Zimmerman 1995). Eventually, this behavior was clearly observed in *P. pipa* as well: Jahn (1982) observed and provided photographs of "sweeping movements" of the hind legs of an amplectant male, movements which served to direct the eggs to "the right place" and "firm them down." [One otherwise reputable book reports that it is the hindlimbs of the female that distribute the eggs across her own back (Stebbins and Cohen 1995).] My observations of *P. pipa* agree with those of Jahn (1982): the amplectant male clearly used his hind feet to reach forward and adpress those eggs that fell onto the anterior portion of the female's dorsum. Rabb (1961) and Rabb and Rabb (1960) had previously attributed implantation of the eggs to the male's clasp and adpressed head, which is undoubtedly the case for the more posteriorly deposited eggs. However, as amplexus is inguinal, the anterior portion of the female's dorsum is not reached by the male's overlapping venter and chin. Indeed, Rabb and coworkers observed only two eggs deposited anterior to the midbody region, and thus this potential function of the stroke was not apparent them. This stroking behavior would be especially useful in pipines, and is in fact most frequently seen, late in the ovipositional period when eggs are being deposited furthest from the male's head, or before and after movements where egg loss is likely, such as those involved in breathing, turnovers, or

fright. Of course, the stroke might be multifunctional, also serving to stimulate or manipulate the female, as Rabb suggested. Indeed, the stroke is also seen in several non-pipine pipids (Rabb and Rabb 1963b) for which egg adpression is not a concern. The occurrence of the behavior in several genera in the small family suggests it might be a shared characteristic, perhaps for female stimulation or manipulation. However, for pipines, it would appear to be an exaptation that now assists with egg adpression.

6. Embryos do not receive sustenance from the female (e.g., Jahn 1982; Halliday and Adler 2002). Although froglets weigh more than eggs (Rabb and Snedigar 1960; Wyman 1854), their dry weights are the same (Rabb 1961). However, the embryos do appear to be receiving some essential substance or hormone from the brood pouch, as fertile eggs that fail to attach develop for approximately two days, to the same stage as eggs becoming enveloped at that time (Iwasawa and Tanaka 1994). In addition to not providing significant nutrition, the pouch might not be particularly well vascularized, as previously reported (Rabb and Snedigar 1960 and therein). Rather, it is lined with a hypertrophied epidermis (Iwasawa and Tanaka 1994), so the embryos might not even be exchanging respiratory gases with the female. Wyman (1854) observed in preserved specimens how the larvae tend to sit on top of the yolk, where they are nearest to the water and in an ideal location for external gas exchange. Iwasawa and Tanaka (1994) described how embryos sometimes protrude their highly vascularized transparent "tails" from the pouches late in gestation, possibly using the structure as a gill analogue. Rabb (1961) first described the highly vascularized tail and speculated on its possible role as a respiratory organ prior to its resorption three weeks before emergence. Rabb and Snedigar (1960) observed a similar structure in late abortions and early births, but were clear to state that this is not a tail, rather it is a vascularized sac protruding from the cloaca. However, Rabb (1969) no longer made the distinction and wrote "Respiration may be helped by a thin membranous out-pocketing from the cloaca, which possibly represents the remains of the tadpole tail."

7. *Pipa pipa* has incredibly small eyes. However, they are not blind or particularly visually impaired, as some authors suggest (e.g., Palmer 1994; Staniszewski 1995; see also comments in Armburst 1979). In fact they see quite well and respond to keepers peering into their enclosures without the vibrational cue of foot movement (pers. obs.). They will also come up to the surface to beg for food when they see a keeper and can readily learn to hand feed, gaping to receive their rations (Armburst 1979; Deckert 1917).

Husbandry Recommendations.—Breeding *Pipa pipa* in captivity has proven challenging. Given the right conditions, newly imported animals will readily engage in amplexus, but rarely oviposit. Unfortunately, most ovipositions that do occur end with all the eggs falling from the female's back. After a decade of working with the species, Brookfield only managed to produce offspring in two of eight breedings (Sughrue 1969). Toronto Zoo produced five offspring from a single fertile clutch, despite over a dozen breeding attempts by the frogs (B. Johnson, pers. comm.). Iwasawa and Tanaka (1994) managed success in only one of eight breedings. Even in full-term pregnancies, perfectly formed froglets sometimes die in or shortly after exiting the maternal chambers (Schüette and Ehrl 1987; pers. obs.). Rabb and Snedigar (1960) and Iwasawa and Tanaka (1993) tried using hormones to induce and maintain breeding condition, but met with negligible success. In the interest of promoting better husbandry to provide more opportunities for studying breeding behavior, I offer the following husbandry advice:

—Re-create a neotropical swamp. These large frogs need a lot of room to move around, and the more volume offered, the easier it will be to maintain water quality. A standard 55-gallon aquarium is minimal for a pair or maybe two if the filtration system is robust and sized to meet their biological filtration needs (see below). Cattle tanks or even small swimming pools are ideal for groups. Water depth is not so important (see misconception #2, above). Water should be warm (24–27°C), soft, acidic (pH = 6.5–6.9 using sphagnum or peat moss, tea bags, and/or oak leaves, which also beneficially stains the water with tannins), and murky (direct light limited). Excellent substrata include Java moss, sphagnum moss (slow to break down, but monitor pH), and leaf litter. The latter two take some time to waterlog, but provide excellent cover (psychological well being) for the frogs. Avoid putting heaters in the tank with the animals, as they might wedge themselves behind the tube and get burned when it activates. I have observed this in *P. parva* on more than one occasion. To avoid this risk, place the heater in a sump.

—Monitor water quality. pH can change, and biological wastes accumulate rapidly, especially in smaller tanks. Pipids generate copious amounts of ammonia (Cragg et al. 1961), which must be removed with manual water changes (can become a daily requirement) or with robust biological filtration. Aeration is not so important for pipids, which rely heavily on pulmonary respiration, but it is important to maintain adequate bacterial colonies in the biological filters (see Zippel 2001). A high dissolved oxygen content might also be required for the embryos (see below).

—Provide good food in abundance. Avoid strips of meat or organs and rodent pups (see Table 3), which seem unnatural. Feed live fish of the appropriate size, but avoid the exclusive use of goldfish, which are fatty and possibly cause hypervitaminosis D (Frye 1992). Also feed earthworms or nightcrawlers from clean sources (some are reported to be toxic [Schüette and Ehrl 1987]), and when they are available, one can supplement with freshwater shrimp, other crustaceans, and tadpoles.

—Odor is a very important breeding stimulus for *P. pipa* (Rabb and Rabb 1963a) and other pipids (Rabb 1963b). Try to maintain males in tanks isolated from the females and isolated from each other. This way, when animals are finally introduced, the encounters are novel and elicit the genuine responses that are gradually lost during the acclimation of cohabitation (pers. obs.). Isolated animals should be fed well, and kept in relatively shallow warm water. See Palmer (1994) regarding the use of cooler maintenance temperatures, although this paper offered so few data that it is difficult to gauge success relative to warmer temperatures. When they are to be introduced, put them into a deeper (preferably several feet, but 45 cm will suffice), cooler (to 21°C) tank to simulate conditions of flooding from the onset of the cool, rainy season. Schüette and Ehrl (1987) successfully used a similar temperature change regime, as did Rabb and Rabb (1963a), unintentionally. The Denver Zoo actually raised temperature (water level same) from 26 to 29°C to stimulate breeding.

—Light quality and duration have been shown to have a signifi-

cant effect on induction of spawning in two species of African pipids. Savage (1965) showed that *Xenopus laevis* spawns more readily in the presence of light vs. complete darkness. Rabb and Rabb (1963b) induced spawning in an inactive group of *Hymenochirus boettgeri* by moving them from under indoor artificial lighting to outdoor natural lighting. The effect of light, however, might occur indirectly via an increase in the concentration of an algal metabolite (Savage 1965). Commercial *Xenopus* breeders keep their isolated males under intense light to simulate the dry season insolation. Palmer (1994) claimed photoperiod decline is important to stimulate breeding in *P. pipa* but did not state how or to what extent it was manipulated.

—The role of auditory cues in inducing reproductive readiness has yet to be fully explored. Rabb (Rabb 1973; Sughrue 1969) was able to induce oviposition in isolated female *Xenopus laevis* and *Pipa parva* simply by playing back the calls of males. Most keepers realize that a metallic tap on the tank can induce calls from the males. Drewes (1977) commented on the role of a nearby garbage compactor in initiating amplexus in his animals. I have heard my males call vigorously in response to a nearby air conditioner, and especially in response to the low, rumbling frequencies of an electric bass guitar.

—The inclusion of certain snails, specifically Indian Tower Snails (*Melanoides tuberculata*), is not recommended, as these animals tend to attack the eggs before they can sink into the dorsum (Schüette and Ehrl 1987).

—Late-term deaths of froglets still in the pouches are not uncommon (e.g., Schüette and Ehrl 1987, pers. obs.). Drewes (1977) had eight such 'stillborns' out of 33 full term young. Schüette and Ehrl (1987) experienced some full-term deaths and even had fungus attack the female's dorsum. The froglets are moving around within the pouch at this stage, and will even feed on live prey (Rabb and Snedigar 1960). They are presumably relying on cutaneous respiration at this stage, so dissolved oxygen levels might be an important factor. Dead froglets should be manually removed from the maternal pouches to prevent infection of neighboring pouches and of the female systemically.

—Once froglets are free-swimming, they are very easy to raise. Feed them heavily on live food items (see Table 3) and watch water quality closely.

—The tadpole-bearing species will readily consume their own young (pers. obs.), while the froglet-bearers do not (Rabb 1961; Rabb and Snedigar 1960; Schüette and Ehrl 1987; pers. obs.). In *P. parva*, hungry cagemates will sometimes also eat newly deposited eggs off the back of a 'gravid' female (pers. obs.); feed heavily and isolate accordingly.

NATURAL HISTORY NOTES

The Natural History Notes section is analogous to Geographic Distribution. Preferred notes should 1) focus on observations with little human intrusion; 2) represent more than the isolated documentation of developmental aberrations; and 3) possess a natural history perspective. Individual notes should, with few exceptions, concern only one species, and authors are requested to choose a keyword or short phrase which best describes the nature of their note (e.g., Reproduction, Morphology, Habitat, etc.). Use of figures to illustrate any data is encouraged, but should replace words rather than embellish them. The section's intent is to convey information rather than demonstrate prose. Articles submitted to this section will be reviewed and edited prior to acceptance.

Electronic submission of manuscripts is requested (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Authors without the ability to send manuscripts electronically may supply hard copy instead. Figures can be submitted electronically as JPG files, although higher resolution TIFF or PDF files will be requested for publication. If figures cannot be provided in this format, you may send them to the section editor for scanning. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ssarherps.org/HRinfo.html. Manuscripts should be sent to the appropriate section editor: **Marc P. Hayes** (amphisbaenids, crocodilians, lizards, and *Sphenodon*; mhayesrana@aol.com); **Charles W. Painter** (amphibians; cpainter@state.nm.us); **Andrew T. Holycross** (snakes; holycross@asu.edu); and **James Harding** (turtles; hardingj@pilot.msu.edu).

Standard format for this section is as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother [2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. Herpetol. Circ. 29:1–82; available online at <http://herplit.com/SSAR/circulars/HC29/Crother.html>]; for Mexico as it appears in Liner [1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*, Herpetol. Circ. 23:1–113]), KEYWORD. DATA on the animal. Place of deposition or intended deposition of specimen(s), and catalog number(s). Then skip a line and close with SUBMITTED BY (give name and address in full—spell out state names—no abbreviations). (NCN) should be used for common name where none is recognized. References may be briefly cited in text (refer to this issue for citation format).

Recommended citation for notes appearing in this section is: Lemos-Espinal, J., and R. E. Ballinger. 1994. *Rhyacosiredon leorae*. Size. Herpetol. Rev. 25:22.

CAUDATA

AMBYSTOMA T. TIGRINUM (Eastern Tiger Salamander). **PAEDOMORPHIC POPULATION.** Examples of paedomorphism can be observed in all caudate families (Duellman and Trueb 1986. Biology of Amphibians. Johns Hopkins University Press, Baltimore. 670 pp.). Paedomorphic individuals have been reported in several species of the genus *Ambystoma*, however paedomorphic *A. t. tigrinum* populations have only been reported in Michigan (Hensley 1964. Herpetologica 20:203–204). This subspecies occurs in bottomlands, open fields, and deciduous and coniferous forests in most of the mid-western and southeastern states (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington. 587 pp.), although records in East Texas are sparse (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station, 421 pp.). This is the first report of a population of paedomorphic *A. t. tigrinum* in Texas.

From 23 Nov to 8 Jan 2005, four paedomorphic *Ambystoma t. tigrinum* were captured in minnow traps placed in a permanent farm pond at Camp Tyler ca. 5 km N of Whitehouse, Smith County, Texas (32°15.267'N, 095°11.645'W). The pond is located in a horse pasture and is ca. 150 m from the closest forest edge. Of the individuals captured, two males were identified by the presence of swollen cloacal vents. The other captures were presumed to be

female due to the absence of swollen vents. This observation coincides with the breeding season of this subspecies that occurs from November through May. Bishop (1943. A Handbook of Salamanders. Comstock Publ., Ithaca, New York. 555 pp.) found that a population of metamorphosing *A. t. tigrinum* averaged 104 mm TL. The sampled individuals in this population were nearly twice as long (mean SVL 89.3 ± 3.2 mm; mean TL 171.3 ± 5.5 mm; mean mass 25.12 ± 2.12 g). Each individual was marked subcutaneously with a PIT tag, photographed, and returned to the pond.

From the same sampling effort, five fully metamorphosed *Ambystoma t. tigrinum* were captured (mean SVL 104.4 ± 8.8 mm; mean TL 207.8 ± 23.4 mm; mean mass was 287.6 ± 84.3 g). All were identified as males by their conspicuously swollen vents.

Previous experiments with hormones have suggested that low activity levels in the hypothalamus, pituitary, and thyroid glands influence the retention of larval characteristics in sexually mature salamanders (Duellman and Trueb, *op. cit.*). It is also known that various agricultural chemicals may cause abnormalities in amphibians (Pough et al., *op. cit.*), however no pesticides or herbicides are used on the vegetation around this pond (A. Byboth, pers. comm.). Therefore, the retention of larval characteristics in this population is likely natural. It has been hypothesized that natural selection might favor paedomorphic individuals when the terrestrial environment is unfavorable (Whiteman 1994. Quart. Rev. Bio. 69:205–221). Lack of refugia or significant leaf litter needed to sustain moisture may create a strenuous habitat to traverse. Selection pressures might therefore favor those individuals that retain larval characteristics and remain in the pond.

Submitted by **PAUL M. HAMPTON**, Department of Biology, University of Texas at Tyler, 3900 University Blvd, Tyler, Texas 75799, USA.

CRYPTOBRANCHUS ALLEGANIENSIS (Hellbender Salamander). **LARVAL DIET.** Several studies document the diet of adult *Cryptobranchus alleganiensis* as consisting primarily of crayfish, but include fishes and their eggs, aquatic insect larvae and adults, worms, mollusks, amphibians (including hellbenders and their eggs), aquatic snakes, and scavenged material (Bishop 1941. The Salamanders of New York. New York State Mus. Bull. No. 324:1–365; Nickerson and Mays 1973. The Hellbenders: North American Giant Salamanders, Milwaukee Pub. Mus. Publ. Biol. Geol No. 1:1–106; Peterson et al. 1989. Southwest. Nat. 34:438–441). Dietary data of larval *C. alleganiensis* are lacking, except for those raised in captivity, which have successfully been reared on brine shrimp and black worms including *Tubifex* (R. Goellner, pers. comm.). This study was conducted to investigate the diet of larval *C. alleganiensis* in the Little River, Tennessee.

Diurnal skin-diving surveys of the Middle Prong and main body of the Little River in the Great Smoky Mountain National Park were conducted from 14 June to 30 July 2003, for a total of 118 h. Surveys were conducted between 0900 and 1930 h and involved 2–10 surveyors. Underwater observations coupled with rock turning were implemented for surveys. Stomach contents of Hellbenders were collected non-lethally via stomach flushing with a 5-cc plastic canula filled with river water; stomach contents were preserved in 70% ethanol. Hellbender larvae were anesthetized in a 0.1% tricaine methylsulfonate (MS-222) solution, weighed with an Ohaus CS-2000 compact scale, measured using a metric ruler for total (TL) and snout–vent (SVL) lengths, and marked via subcutaneous injection of acrylic polymers (Johnson and Wallace 2002. Herpetol. Rev. 33:29–32). Needles were sterilized in 95% ethanol before each use. Larvae were allowed time to fully revive from anesthetization before being released at their capture site. Global positioning satellite (GPS) locations were recorded at each capture site. Qualitative macroinvertebrate samples from each site were collected using a D-frame dip net with 500 µn mesh. Rocks immediately upstream of the net were brushed for macroinvertebrates. All samples were preserved in 70% ethanol. Stomach and macroinvertebrate samples were analyzed using a Bausch and Lomb 0.7x–3x dissecting scope.

One large gilled larval *C. alleganiensis* (13 cm TL, 9 cm SVL, 17 g) was captured in 80 cm deep water, 205 cm from the bank, at 20°C water temperature. It was found between two rocks that were ca. 8 x 34 x 22 cm and 15 x 48 x 27 cm. Stomach contents included remains of Megaloptera, Ephemeroptera (Ephemerellidae and Heptageniidae), Diptera pupae, and wings from unidentifed aquatic insects. A second non-gilled larval *C. alleganiensis* (15 cm TL, 9.5 cm SVL, 18 g) had an empty stomach.

The stomach sample suggests larger larval and adult aquatic insects as the main prey for larval *C. alleganiensis* in Little River. Further sampling will be required to further elucidate the diet of larval hellbenders.

This study was conducted under the Great Smoky Mountains National Park Permit GRSM-2003-SCI-0051. We thank K. Voorhis, GSMIT's staff and interns, Ripley's Aquarium of the Smokies staff, D. Robinson, and K. Landgon for providing continued support, and K. Krysko for manuscript critique.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander). **MORPHOLOGY/PHENOLOGY**. Prior to our study *Hemidactylium scutatum* larvae had not been recorded in Maine, where the species is listed as Special Concern. We describe field characteristics to improve discrimination between *H. scutatum* and larvae of a co-occurring species, Red-spotted Newts (*Notophthalmus viridescens viridescens*) in the field. *Hemidactylium scutatum* larvae are adapted to lentic, low oxygen environments and are classified as "pond-type larvae," defined by large, bushy external gills and a long fin fold that extends well up onto the body near the shoulder region (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington. 587 pp.). *Ambystoma* spp. and *N. v. viridescens* are co-occurring species with pond-type larvae. *Ambystoma* spp. develop earlier than *H. scutatum* larvae in our area, but larval *N. v. viridescens* can co-occur with *H. scutatum* larvae, making field identification difficult. Newly-hatched *H. scutatum* lack balancers, distinguishing them from newly-hatched *N. v. viridescens* (Bishop 1941. The Salamanders of New York. New York State Mus. Bull. 324:11–17; 174–189; Richmond 1999. Ph.D. Diss. Univ.

Massachusetts, Amherst. 305 pp.). Balancers may be difficult to see in the field. Identification of larval *H. scutatum* is complicated by the variable number of toes (0–4) at different stages of development (Bishop 1941, *op.cit.*), however, older *H. scutatum* larvae have four toes on each rear foot, larval *N. v. viridescens* have five (Petranka 1998, *op. cit.*).

During 2001, we collected 2 *H. scutatum* eggs from a wetland in Acadia National Park (ANP), Maine, to identify distinguishing characteristics during larval development. We incubated eggs in *Sphagnum* sp. suspended above water in an aquarium, and we maintained them to hatching at ambient temperature in a shaded, un-airconditioned building. We also captured six larval *N. v. viridescens* from the same wetland and aquarium-raised the larvae for comparison with *H. scutatum* larvae. Organic matter and water from the natal pond provided food for the developing larvae. We also dipnetted wild larvae from small pools of water (11 in ANP; 3 in the University of Maine Demeritt Forest [DF]) in late July (i.e., near metamorphosis) 2002–2004 in wetlands with high numbers (i.e., 6–33) of *H. scutatum* nests.

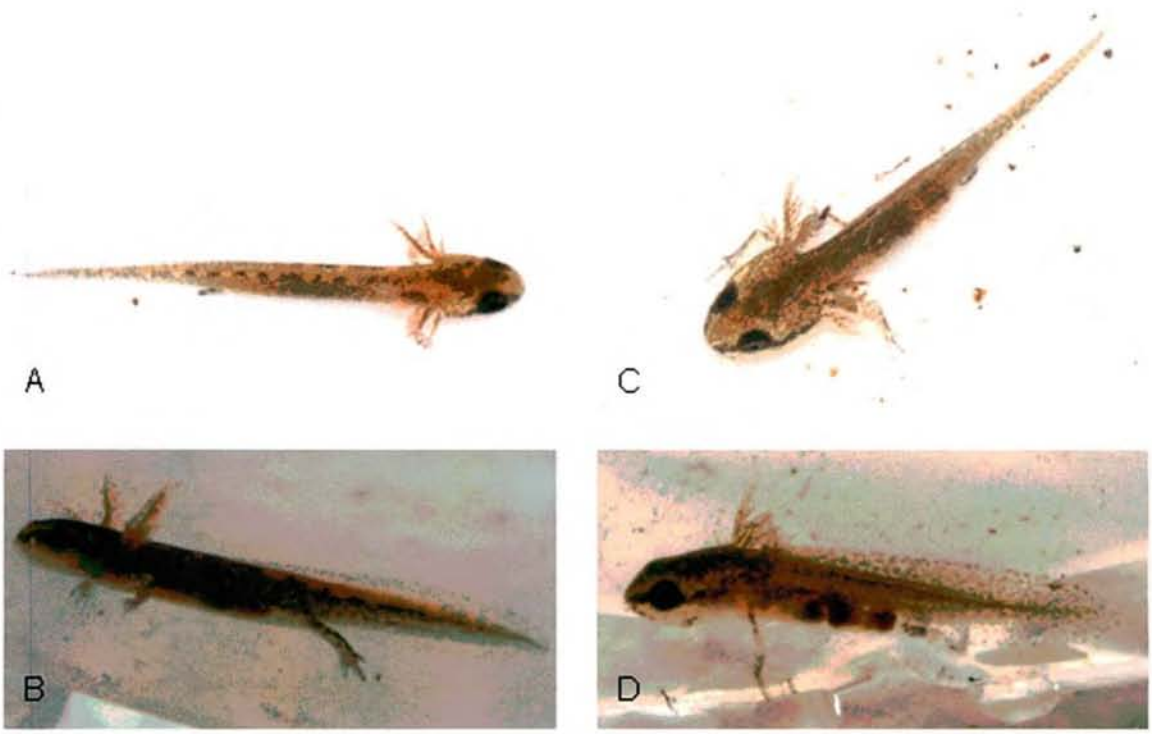

FIG. 1. Comparison of *H. scutatum* larvae (a) newly hatched (27 June 2004) and (b) near metamorphosis (22 July 2004) with *N. v. viridescens* larvae (25 July 2004) (c) and (d) in Maine.

Captive-hatched and captive-raised larvae.—We observed *H. scutatum* embryos hatching 18 June 2001 at 10 mm total length (TL), less than the 11–14 mm TL reported by Bishop (1941, *op. cit.*). By 9 July the *H. scutatum* larvae were 10 mm SVL and 18–19 mm TL, translucent yellow-brown, and one larva had toes on its rear limbs. By 17 July larvae were 19 mm TL and retained a dorsal fin extending onto the body. Larvae moved little, infrequently swimming and settling to the bottom with legs extended. Larvae metamorphosed (e.g., rusty dorsum, red gills, no dorsal fin) 38 and 42 days after hatching.

Wild larvae near metamorphosis.—Larval *H. scutatum* collected from ANP wetlands were 12.1 ± 0.56 mm SVL (N = 7; mean ± SD mm), and TL for larvae with uninjured tails was 21.1 ± 2.14 mm (N = 4). Size (18–23 mm uninjured TL; 3 mm head width; 1 mm body width) indicated they were near metamorphosis (pers. obs.; Blanchard 1923. Amer. Nat. 57:262–268).

A dark color surrounded the golden eyes with round, black pupils, and a dark line crossed the eye and extended onto the face (Fig. 1a, b). Chin and throat were a cream color that tapered off beyond the gills and front legs (Fig. 1b). The belly was no longer yellow. Gills were a rust color. A dark Y-shaped mark was on the head (Fig. 1a). The dorsum was rust colored, extending as a stripe under the fin to the tip of the tail (Fig. 1b), with rust spots alternating with dark mottles at the edge, and with tiny dark flecks throughout (Fig. 1a). Larvae had a thin, clear, speckled top fin on the tail that no longer extended onto the body (Fig. 1b). Each foot had four toes, and toes on the front feet were shorter (Fig. 1b) than those of *N. v. viridescens* (Fig. 1c). Larvae appeared exactly as drawn in Bishop (1941, *op. cit*) and closely resembled drawings in Parmelee et al. (2002. A Field Guide to Amphibian Larvae and Eggs of Minnesota, Wisconsin, and Iowa. U.S. Geol. Surv., Biol. Res. Div., Information and Technology Report USGS/BRD/ITR-2002-0004, Washington, D.C. iv + 38 pp.). Coloration resembled that of drawings in Dodd (2003. Monitoring Amphibians in Great Smoky Mountains National Park. U.S. Geol. Surv., Biol. Res. Div., Circ. 1258, Tallahassee, Florida vi + 127 pp.).

Distinguishing H. scutatum *from* N. v. viridescens *larvae.*—At TL < 18 mm, larvae of the two species resembled one another; both species were translucent, pale yellow-brown, without visible rear toes, and both had a tail fin that extended onto the dorsal surface of the body (Fig. 1a, c, d). However, *H. scutatum* larvae could be distinguished by a dark Y-shape mark on the head, rust dorsal mottles, with some dark mottles and short toes on the front

TABLE 1. Gender variation in snout–vent length (SVL), total length (TL), and mass for a gilled population of *Notopthalamus viridescens*.

Gender	N	SVL (mm)	TL (mm)	Mass (g)
Male	9	40.2 ± 2.8	84.7 ± 4.7	2.02 ± 0.35
Female	4	45.3 ± 5.7	94.3 ± 1.7	3.45 ± 1.06
Total	13	41.5 ± 4.0	87.1 ± 7.8	2.49 ± 0.88

feet (Fig. 1b), unlike *N. v. viridescens* larvae, which had no Y mark, few dorsal mottles, and longer toes (Fig. 1c, d). Coloration was a distinguishing feature when larvae were 18–23 mm TL: *N. viridescens* larvae continued to be yellow with a tall, thin keel on the tail (Fig. 1d), whereas *H. scutatum* larvae had a ruddy dorsum, mottled dark sides, pale belly, patterned head, and little or no keel on the tail (Fig. 1b). The eyeline was present at and just beyond the eye on *H. scutatum*, whereas on several *N. viridescens*, the eyeline extended into a stripe to the tip of the tail. *Notophthalmus viridescens* larvae were more active than *H. scutatum*, which were usually stationary except for occasional surfacing for air.

Phenology.—Larvae were observed hatching at field-located nests as early as 16 June and reached metamorphosis as late as 31 July in Maine (Chalmers. 2004. M.S. thesis. University of Maine, Orono, Maine. 109 pp.). The larval period ends soon after larvae reach a total length of ca. 18–23 mm and adult coloration develops. At the conclusion of our study, one *H. scutatum* larval reference specimen was deposited at the ANP museum.

Submitted by **REBECCA J. CHALMERS**, Patuxent Wildlife Research Center, 12100 Beech Forest Road, Laurel, Maryland 20708-4038, USA (e-mail: chalmersbecky@yahoo.com); and **CYNTHIA S. LOFTIN**, USGS Maine Cooperative Fish and Wildlife Research Unit, 5755 Nutting Hall, University of Maine, Orono, Maine 04469-5755, USA (e-mail: Cyndy_Loftin@apollo.umenfa.maine.edu).

NOTOPTHALAMUS VIRIDESCENS LOUISISANENSIS (Eastern Newt). **POPULATION OF GILLED ADULTS.** The Eastern Newt can be found throughout the eastern United States and localities have been documented throughout most of East Texas (Dixon, 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station, 421 pp.). For most populations of *Notophthalmus viridescens*, following a period of aquatic development, the larvae transform into a terrestrial red eft stage. This juvenile stage may last for several years before the eft returns to a breeding site and transforms into an aquatic adult. Generally, aquatic adults lack gills and retain lungs from their terrestrial stage, however, some populations are comprised of gilled adults. In populations of gilled adult *N. viridescens*, the terrestrial eft stage is omitted and maturation occurs in an aquatic environment. These individuals experience partial metamorphosis but retain gills and structures associated with larvae, such as extensive tail fins (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington. 587 pp.). Reported populations of gilled adults are erratic within the species' range. Populations have been reported from Florida, Illinois, Indiana, Louisiana, Massachusetts, New Jersey, New York, North Carolina, and Tennessee (reviewed in Petranka, *op. cit.*). This article is the first documentation of a gilled population of *N. viridescens* in Texas.

On 8 Dec 2004, two gilled *Notophthalmus viridescens louisianensis* were collected from a minnow trap placed in a permanent farm pond at Camp Tyler ca. 5 km north of Whitehouse, Smith County, Texas (32°15.267'N; 095°11.645'W). The pond is located in a horse pasture and is ca. 150 m away from the closest forest edge. One female (2.9 g; 42 mm SVL; 89 mm TL) was identified by the lack of a swollen cloaca and the conspicuously distended body associated with gravid females. Another individual was identified as a male (1.8 g; 38 mm SVL; 78 mm TL) by a distinctly swollen vent, cornified toe tips, and hard black pads on the inner thighs indicative of males during their mating season (Petranka, *op. cit.*). Both individuals were morphologically similar to common aquatic adults despite the presence of gills. On 27 Jan 2005, another male and female were found amplexed in a minnow trap. The male was grasping the female just in front of her anterior limbs with his posterior limbs, similar to the beginning of *N. viridescens* courtship described by Hardy and Dent (1988. Copeia 1988:789–792). The amplexed pair was returned to the lab and on 29 Jan 2005, ca. 12 eggs were found in the bottom of their tank. This evidence of maturity and reproduction coincides with the breeding season of this species in the southern United States (Petranka, *op. cit.*). During the trapping period three gilled males were found dead in the mesh of minnow traps. These specimens were deposited in the University of Texas at Arlington (UTA A 56733–35). A total of 13 individuals were captured throughout the sampling period. Size variation for males and females is reported in Table 1.

It has been suggested that the probability of a gilled population of *Notophthalmus viridescens* includes both genetic and environmental factors (Petranka, *op. cit.*). When terrestrial conditions are too harsh, selection should favor individuals that remain in the aquatic habitat. The habitat surrounding the study pond is comprised of short vegetation and lacks refugia. This may create a habitat that is difficult for red efts to traverse or survive in resulting in selection for aquatic maturation (Whiteman 1994. Quart. Rev. Bio. 69:205–221). It has been shown that some agricultural chemicals might influence amphibian development (Pough et al. 2004. Herpetology. Pearson Prentice Hall. 726 pp.). However, at this site, no pesticides or herbicides are used on the vegetation (A. Byboth, pers. comm.), suggesting there is no anthropogenic influence on the physiology of this population.

TARICHA GRANULOSA (Rough-skinned Newt). **SUMMER HABITAT AND AGGREGATION.** Terrestrial behavior and habitat associations of post-metamorphic *Taricha granulosa* are poorly understood (Oliver and McCurdy 1974. Can. J. Zool. 52:541–545; Pimentel 1960. Amer. Midl. Nat. 63:470–496). Chandler (1918. Oregon Agric. Coll. Exper. Sta. Bull. 152:6) referenced Fall *T. granulosa* aggregations in "cavities under stumps, logs, and stones," but does not present specific data. Pimentel (*op. cit.*) reported that *T. granulosa* constructed burrows in a terrarium and 1–3 adults of both sexes shared burrows for up to three months. Here, I describe two summer aggregations of *T. granulosa* from the Willow Creek Natural Area (WCNA) in the southern Willamette Valley, Oregon, USA. The WCNA includes wetlands (primarily seasonal), prairies, riparian forests of willow (*Salix* spp.), black cottonwood (*Populus trichocarpa*), and Oregon ash (*Fraxinus latifolia*), and patches of upland forest of Oregon white oak (*Quercus garryana*), California black oak (*Quercus kelloggii*), and Douglas fir (*Pseudotsuga menziesii*). *Taricha granulosa* commonly breed in old stock ponds and beaver impoundments on the site.

One *T. granulosa* aggregation was found between plywood sheets at a collapsed cabin on 18 July 1996 (UTM 10 485569E 4875494N; elev. 120 m). The aggregation was within a 7.3-ha stand of Oregon white oak (75–100 yrs old) with nonnative Himalayan blackberry (*Rubus armeniacus*) and scattered Douglas fir. This oak stand was bounded by a paved road, a gravel driveway, and upland prairie with a seasonally flooded swale. The aggregation included 30 *T. granulosa* of both sexes (range 35–70 mm SVL), which were tightly clustered and usually in contact with > 1 other individual. This aggregation likely contained multiple age classes. *Taricha granulosa* at WCNA metamorphose at 30–35 mm SVL, and adults at breeding sites in spring are 50–72 mm SVL (CAP, unpubl. data). Condensation between the plywood sheets indicated that interior humidity was noticeably higher than in leaf litter away from the woodpile. The nearest known *T. granulosa* breeding site was a temporary stock pond (20 x 20 x 0.5 m) located ca. 150 m ESE of the aggregation.

The second *T. granulosa* aggregation was found in a 0.86-ha stand of Oregon white oak (75–100 years old) on 04 August 1996 (UTM 10 486549E 4874884N; elev. 142 m). The aggregation of 10 *T. granulosa* included juveniles and adults of both sexes (size data not collected). The newts were curled closely with one another, and were very lethargic upon extraction. The aggregation site was in a cavity beneath a partially uprooted Oregon white oak stump, which was loosely filled with oak leaves, humus, silty/clay loam and cobbles. The aggregation site was ca. 50 m N of a permanent stock pond (20 x 10 x 0.7 m deep) that supports a large *T. granulosa* breeding population in spring (unpubl. data). The oak stand is bounded by a paved two-lane arterial road on one side (ca. 60 m upslope of the aggregation site and the pond); the remainder of the oak patch was bordered by > 10 ha of upland prairie beyond a narrow ring (5–10 m wide) of Himalayan blackberry. The distances between the two aggregations described here and their respective nearest potential breeding habitat are similar to those of Pimentel (1960, *op. cit.*), who estimated that > 90% of *T. granulosa* enter the ground within 200 yards (183 m) of their breeding ponds.

Aggregations of *T. granulosa* are common in aquatic breeding sites (Twitty 1942. Copeia 1942:65–76; Coates et al. 1970. Copeia 1970:177–179; Farner and Kezer 1953. Am. Midl. Nat. 50:448–462). Detailed descriptions of terrestrial aggregations of *T. granulosa* appear to be limited to those of Farner and Kezer (*op. cit.*; p. 452), who reported "large numbers under the rocks and driftwood along the shore" of Crater Lake. Similar to my observations, those *T. granulosa* groups ranged from "newly metamorphosed to large adults" (75–180 mm total length) and "appeared desiccated and sluggish" (Farner and Kezer, *op. cit.*; p. 452). My observations and those of Pimentel (*op. cit.*) and Farner and Kezer (*op. cit.*) indicate that *T. granulosa* aggregate on land and in water in groups that include multiple age classes and both sexes. These observations also may suggest that above- and below-ground microhabitats that are humid, thermally stable, and within 200 m to breeding sites may be valuable to *T. granulosa* in their terrestrial stages.

I thank E. Alverson and K. O. Richter for helpful reviews of this manuscript. The Nature Conservancy and Bonneville Power Administration provided funding and logistical support.

ANURA

BUFO MARGARITIFER (South American Common Toad). **GEOPHAGY.** The *Bufo margaritifer* complex is widely distributed in Latin America, known throughout the Amazon Basin and parts of Panama (IUCN, Conservation International, and NatureServe. 2004. Global Amphibian Assessment. www.globalamphibians.org 27 Dec 2004). This taxon is abundant within the area of the Tiputini Biodiversity Station – Universidad San Francisco de Quito, Yasuní Biosphere Reserve, Napo Province, Ecuador (00°38'18"S; 76°08'56"W). The diet of this species consists primarily of large ants (> 17 mm) and beetles, along with other single prey items (Duellman 1978. Misc. Publ. Mus. Nat. Hist., Univ. Kansas 65:1–352). We observed the practice of geophagy, the consumption of soil, by *B. margaritifer* in the wild and this may represent the first report of geophagy in an anuran.

Geophagy has been observed in mammals, birds, reptiles, butterflies, and isopods on every continent except Antarctica (Brightsmith 2004. Wilson Bull. 116:134–145). On 2 Nov 2002 ca. 2100 h, a *B. margaritifer* was observed with its mouth open in a patch of mud along a trail in *terra firme* lowland rainforest (Fig. 1, top). The individual was observed closing and retracting the eyes into the orbit, in the typical fashion of anurans when swallowing. The individual was removed and placed ca. 1 m from the mud, it proceeded to return to the mud and continue consumption. It was photographed and low-res video taken of the behavior. Upon return, ca. 1.5 h later, the individual was in the same location and appeared to still be consuming the mud, although its head was now beneath the surface of the mud and hence, retraction of the eyes could not be observed. On 22 June 2004 at 1203 h, a second *B. margaritifer* was observed head down in a small mud puddle on a trail in *terra firme* lowland rainforest. The individual was observed raising its head from the surface of the water and then lowering it and placing its mouth at the edge of the mud puddle. On 06 July 2004 at 0031 h, a third *B. margaritifer* was observed with its head down in a mud puddle with hindlimbs dramatically vertical in the air along a trail in várzea (seasonally-flooded lowland rainforest). When removed from the mud puddle this same individual moved immediately back to the puddle and returned to the same position, forcibly pushing its head into the muddy bottom of the puddle using its forelimbs and hindlimbs (Fig. 1, bottom). On 11 Aug 2004 at 1740 h, a fourth *B. margaritifer* was observed in a mud puddle of a trail in várzea forest, its head pressed into the muddy edge just below the surface of the water.

Adult anurans are not known to drink water, except when subjected to particular physiological stresses in a laboratory situation (Duellman and Trueb 1994. Biology of Amphibians. The John Hopkins Univ. Press, Baltimore, Maryland, 670 pp.; Stebbins and Cohen 1995. A Natural History of Amphibians, Princeton University Press, Princeton, New Jersey, 316 pp.). In the genus *Bufo*, the highly vascularized dermis of the ventral pelvic region is the primary area identified for water absorption (Duellman and Trueb 1994, *op. cit.*). This morphological adaptation, the observed behavior and current explanations of geophagy lead to our working hypothesis that here, the practice of geophagy is for the purpose

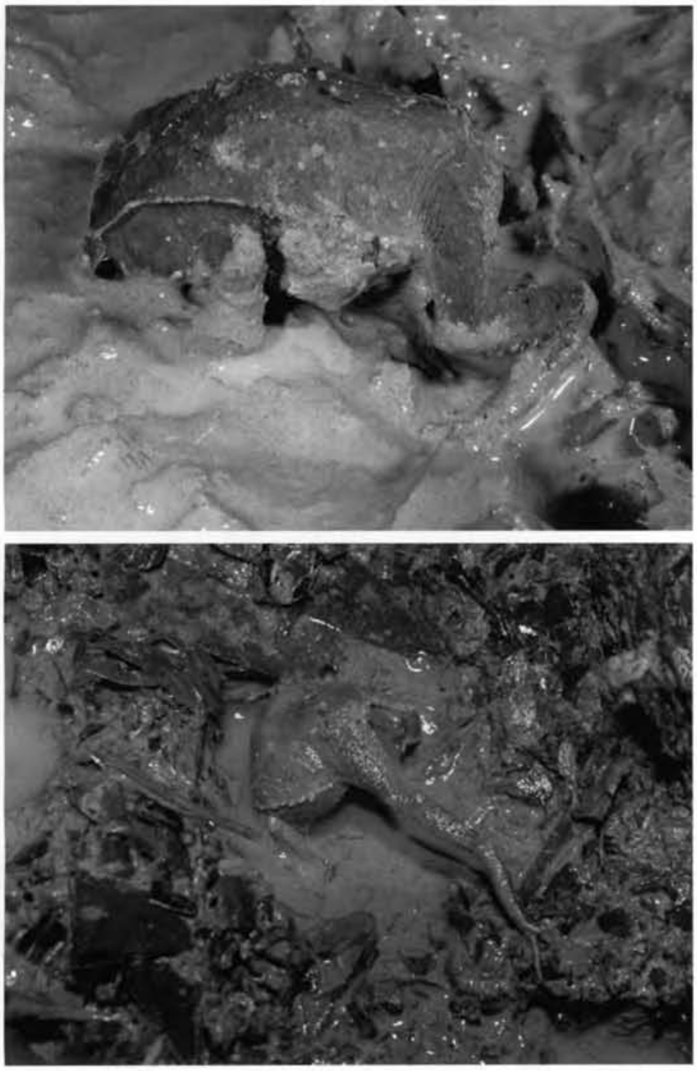

FIG. 1. Top: *Bufo margaritifer* consuming mud from a trail in *terra firme* lowland rainforest. Bottom: *B. margaritifer* returning to puddle after being removed and forcibly pushing its head into the muddy bottom of the puddle using its forelimbs and hindlimbs.

of neutralizing the toxins acquired in their primarily ant diet. Taxa within the order Hymenoptera, particularly ants, have been found to be the most toxic members of the insect world (Meyer 1996. Most Toxic Venom. Chapter 23 *in* University of Florida Book of Insect Records, 2005. <http://ufbir.ifas.ufl.edu/>). This may represent a mechanism for coping with ants as a primary dietary resource.

We thank Bejat McCracken for photography, videography, and field assistance, Paul Herbertson of King's College - London for field assistance, David Romo and Kelly Swing of the Tiputini Biodiversity Station, Universidad San Francisco de Quito, Ecuador. Financial support provided by the TADPOLE Organization.

CHIASMOCELIS CAPIXABA (NCN). **PREDATION**. Species of the genus *Chiasmocelis* breed at temporary ponds in forests (Cruz et al. 1997. Alytes 15:49–47). On 26 Dec 2002 a juvenile colubrid snake, *Liophis poecylogirus* (344 mm TL), was observed capturing a *C. capixaba* at a temporary pond inside a cocoa (*Teobroma cacao*) plantation with an alluvial forest on the left margin of the Doce River, near Povoação (19°33'S, 39°46'W, sea level), 30 km from the town of Linhares, Espirito Santo, Brazil. At this site several male *C. capixaba* were calling along with *C. schubarti*, *Stereocyclops incrassatus*, *Dasypops schirchi*, *Phrynohyas mesophaea*, and *Scinax argyreornatus*.

The snake was captured, and during transportation to the laboratory regurgitated 18 specimens of *C. capixaba* (mean SVL 14.1 mm; range 13.1–15.4 mm; SD 0.54 mm; N = 14) in different stages of digestion. There was no other prey in the stomach contents. Specimens were deposited at Museu de Biologia Mello Leitão – MBML, Santa Teresa, Espírito Santo (*C. capixaba*: MBML 2856–66; *L. poecylogirus* MBML 1427)

DENDROBATES PUMILIO (Poison Frog). **POISONING.** During a field study of *Dendrobates pumilio* in the proximity of the NAIRI field station in Barbilla National Park, Costa Rica, I experienced what I believe to be poisoning from a dendrobatid frog. Within a minute of handling wild *D. pumilio* on 5 January 2001 I sat down to have lunch without first washing my hands. The first sign of poisoning was a burning sensation on the tongue and the palate. A feeling of soreness followed shortly thereafter. The sensation spread posteriorly through the palate to the throat and part of the nasal area. This was followed by numbness of the lips, which later changed to a pricking feeling similar to that experienced after the administration of local anesthesia. Intense pain and discomfort persisted for the remainder of the day, making it difficult for me to consume food or water. The following day the pain was reduced, but became amplified when I attempted to consume food or water. By the end of the third day all signs of poisoning were gone. Problems other than pain and discomfort in the mouth and throat were never experienced.

I believe that these symptoms represent ingestion of toxins from *D. pumilio* because of the high likelihood of transfer of these chemicals to my food and because my symptoms were similar to those described by Daly and Myers (1967. Science 156: 970–973). These authors have worked extensively with poison frogs and reported that *D. pumilio* from the Bocas del Toro archipelago in Panama "...secrete an unpleasant tasting, toxic milky fluid when injured..." and that "...small quantities of the purified toxic principles cause the human throat to tighten...". Dendrobatid frogs, including *D. pumilio*, contain a variety of alkaloids and there is great variation in the presence of alkaloids among populations of *D. pumilio*. Furthermore, the toxicity of the frogs is related to these variations in alkaloids and therefore some populations of *D. pumilio* are more

toxic than others (Daly and Myers 1967, *op. cit.*). The chemistry of the population that inhabits Barbilla National Park is not documented. However, my experiences may suggest that they are toxic enough to cause an unpleasant reaction in humans. Interestingly, human taste has been a widely used technique to detect the presence of chemical compounds in frog skins (Daly et al. 1987. Toxicon 25:1023–1095). However, based on my experiences I do not recommend this technique. Although I did not experience serious illness other than pain and discomfort, I strongly recommended that those working with dendrobatids wash their hands after handling these frogs and avoid situations in which toxins might enter the body via open wounds, the mouth, or thin membranes such as the eyes.

I am grateful to Rainer Schulte for encouraging me to write this paper and to Ingemar Hedström who brought me to Barbilla National Park. Thanks also to Ben Phillips, Ric Shine, Craig Guyer, and an anonymous reviewer whose comments greatly helped to improve the manuscript.

ELEUTHERODACTYLUS BUCCINATOR (NCN). **COLOR VARIATION.** *Eleutherodactylus buccinator* occurs in lowland rainforests in southeastern and northeastern Perú (Rodríguez 1994. Alytes 12:49–63; Rodríguez and Knell 2003. *In* Pitman et al. [eds.], Perú: Yavarí, Rapid Biological Inventories Report 11, pp. 147–150. The Field Museum, Chicago, Illinois). Coloration in life is characterized by a copper-brown dorsal surface, brown-gray flanks, dull pink-orange groin and rear shanks, a cream venter, and light brown spots on the throat (Rodríguez 1994, *op. cit.*). Here, we report on color pattern variation in juvenile and adult individuals observed during a herpetofauna inventory (2001–2003) at Río Los Amigos Research Center (12°34'S, 70°06'W; 270 m elev.), Madre de Dios department, Perú.

Of 25 specimens observed, only 8 individuals (32%) matched the original color pattern description (Rodríguez 1994, *op. cit.*). The remaining individuals exhibited a variation from this pattern: 13 individuals (52%) exhibited pale brown-gray (instead of pink-orange) groin and rear shanks and 4 individuals (16%) exhibited yellowish cream arms (instead of brown arms) bearing 0–4 black spots. In addition, one of the latter individuals exhibited a yellowish cream spot below the tympanum and the same color on knees and heels. This variation is important because pink-orange groin and rear shanks were considered a diagnostic characteristic (Rodríguez 1994, *op. cit.*) and is the typical pattern observed at the type locality (Cocha Cashu Biological Station, ca. 150 km NW from Río Los Amigos Research Center). Individuals of the three color variants occurred in terra firme and floodplain forest, the two forest types that cover most of the area. This report increases the number of *Eleutherodactylus* species (more than 77) known to exhibit color or dorsal pattern polymorphism (Hoffman and Blouin 2000. Biol. J. Linn. Soc. 70:633–665).

Specimens were deposited in the herpetology collection at the Museo de Historia Natural Universidad Nacional Mayor de San Marcos (MHNSM 23100-23103), Lima, Perú. Photographic records will be deposited in the AmphibiaWeb digital collection, University of California, Berkeley.

Benavides 5440, Surco, Lima 33, Perú (email: emmmueller@yahoo.com).

OSTEOPILUS SEPTENTRIONALIS (Cuban Tree Frog). **COLONIZATION OF THE BRITISH VIRGIN ISLANDS.** Native to Cuba, the Cayman Islands, and the Bahamas, *Osteopilus septentrionalis* is widely introduced in the Caribbean and elsewhere (Lever 2003. Naturalized Reptiles and Amphibians of the World. Oxford University Press, New York. 318 pp.). It has only been reported in the British Virgin Islands (BVI) once, from Necker Island (Lever, *op. cit.*). Here we document the ongoing spread of *O. septentrionalis* across the BVI. GPS points are based on the WGS84 datum and all specimens were verified by Jose Rosado, Museum of Comparative Zoology (MCZ).

The first record of *O.* septentrionalis in the BVI (MCZ A-135386) was collected on Tortola at the Road Town dock (18°25.8'N, 64°36.8'W) during Fall 1990 by Everton Henry. The species is currently abundant throughout the island. Because the frog breeds in cisterns providing residential water, it is considered a pest and attempts are made by the local health authorities to remove it from specific locations. The second oldest specimen (MCZ A-119258) was captured on Necker Island (18°31.6'N, 64°21.6'W) on 19 Oct 1993 by A. Miller. No population was established (Meshaka 1996. Herpetol. Rev. 27:37–40; unpubl. obser.). The first collection on Beef Island (MCZ A-136611) was made at Trellis Bay (near the international airport, 18°26.44'N, 64°32.08'W) on 15 Oct 2002 by Gad Perry and Kate LeVering. Additional sites with breeding populations have since been identified on Beef island, which is connected to Tortola by a bridge and frequent traffic. One of these sites is a nursery, which supplies ornamental plants to many BVI establishments. The following year marked the first record of the species on Virgin Gorda (MCZ A-136432). The specimen was collected by Jim Egelhoff on 27 Oct 2003 in Spanish Town (18°26.6'N, 64°26.2'W). More extensive work in 2004 revealed the presence of a breeding population in the town. Most recently, a collection (field tag JO166) was made on Peter Island (18°21.231'N, 64°34.317'W) by Jennifer Owen and Gad Perry on 13 Oct 2004. Frogs are established at several locations on the island, suggesting a breeding population.

There appears to have been multiple introductions of the frog in the BVI, primarily through movement of cargo and ornamental plants. The Necker Island specimen was associated with ornamental plants arriving from Miami (Meshaka, *op. cit.*). BVI resident Elvit Meyers (interviewed October 2002) reported frogs arriving in Cane Garden Bay, Tortola during April 2000, long after the initial specimen was collected there. The frogs were located in concrete block pallets arriving from Florida and local populations then rapidly expanded. Other populations, such as Beef Island and Peter Island, may be the result of spread within the BVI, although human assistance may have been involved. As *O. septentrionalis* preys on native species (Lever, *op. cit.*), the ongoing range expansion of the species is a source of concern.

PEDOSTIBES TUBERCULOSUS (Malabar Tree Toad). **ADVERTISEMENT CALL AND DISTRIBUTION.** Advertisement call patterns of anurans provide insights into speciation, territoriality, evolution, and phylogeny as these patterns reveal the species identification and motivation to mate (Bridges and Dorcas 2000. Copeia 2000:587–592; Emerson 2001. *In* Ryan [ed.], Anuran Communication, pp. 36–43. Smithsonian Inst. Press. Washington, D.C.). Anuran acoustics have been studied for 20 of the 113 species known from Western Ghats (Gururaja 2004. Sahyadri Mandooka: Amphibians of Western Ghats; Kadadevaru and Kanamadi 2001. Curr. Sci. 80:1486–1487; Kuramoto and Joshy 2001. Curr. Herpetol. 20:85–95). Herein we report on advertisement call, explosive breeding behavior, and distribution of *Pedostibes tuberculosus*, endemic to Western Ghats.

Pedostibes tuberculosus is a medium-sized tree toad (mean SVL ± SE: 37.18 ± 0.44 mm; range: 36–38 mm; all male, N = 4, Fig. 1). Individuals have a distinct sub-gular vocal sac. Calls of four individuals (ca. 1.3 m above ground) were recorded at 15-minute intervals using an Olympus digital voice recorder W-10 as Differential Pulse Code Modulation at 15.5 kHz. Calls were recorded less than 30 cm from the specimen amidst evergreen-semi-evergreen forest (RH 97%, 23.6°C) adjacent to a small perennial stream (marked in Fig. 2).

FIG. 1. *Pedostibes tuberculosus* (male, 38 mm SVL) at Jakkanagadde, Shimoga, Karnataka. Scale bar: 10 mm.

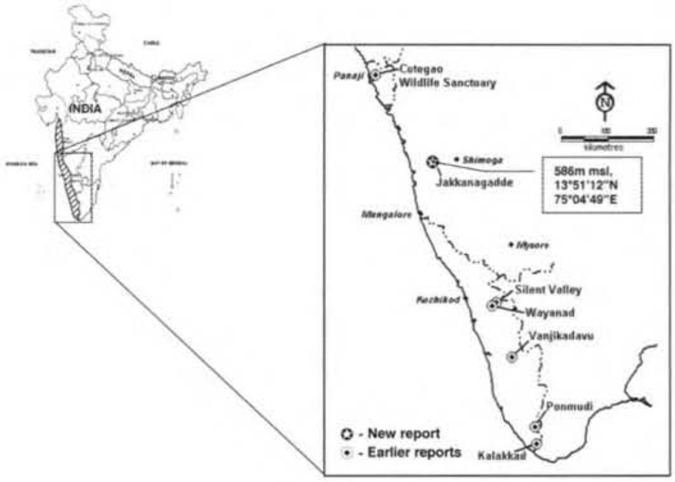

FIG. 2. Reported sightings of *Pedostibes tuberculosus* in Western Ghats.

Calls were single and chorus, and antiphonal, heard for a month with the onset of southwest monsoon (June 2004). Chorus calls were synchronous, starting with an individual's initiation. Single calls of *P. tuberculosus* were analyzed as per Littlejohn (2001. *In* Ryan [ed.], Anuran Communication, pp. 102–120. Smithsonian Inst. Press. Washington, D.C.). Each call lasted for 3–7 sec, and had 14–37 pulse groups (PG) of 3–11 pulses with the domination of 4–8 PG, of which PG 1–2 (N = 16) had a larger period (145.63 ± 21.72 ms) and interval (117.69 ± 22.09 ms) in the entire call series. Pulse frequency was 12.87–44.67 (34.82 ± 3.83). PG period was 61–134 ms. Amplitudes of the first and last pulses of the first and last pulse groups were low compared to others. Dominant frequency was 3782.13 ± 30.58 Hz. Pulse groups sounded like *Shchirrrrrr shirrrr shirrr shirrr shirrr.....*

Call structure of *P. tuberculosus* varies considerably from other bufonids in Western Ghats (Kanamadi et al. 1995. J. Adv. Zool. 16:5–11). Mean pulse rate of *Bufo melanostictus* was twice that of *P. tuberculosus*. However, similarity was noticed between the pulse rate of *B. fergusonii* and *P. tuberculosus*. The dominant frequency in *B. melanostictus* was 1450 Hz, in *B. fergusonii* it was 3175 Hz, and in *P. tuberculosus* 3782 Hz. Synchronous calls in *B. americanus*, *B. bombina*, *B. variegata*, *B. melanostictus*, and *B. fergusonii* are attributed to explosive breeding behavior (Duellman and Trueb 1986. The Biology of Amphibians. McGraw-Hill Book Inc., New York. 670 pp.; Kanamadi et al. 1995, *op. cit.*). The same can be implied for *P. tuberculosus* which has a similar call pattern. Even though its presence was predicted (Biju 2001. Indian Soc. Cons. Biol. 1:1–24; Das and Whitaker 1998. Herpetol. Rev. 29:173), there are no earlier reports of *P. tuberculosus* from Karnataka spanning over 400 km of Western Ghats (earlier reports are marked in Fig. 2). The new location is ca. 333 km N of Silent Valley (nearest southern range) and 222 km S of Cotegao Wildlife Sanctuary (nearest northern range).

We thank the ISRO-IISc-Space Technology Cell; the Ministry

of Environment and Forests, GOI; Indian Institute of Science for financial and infrastructure support. We thank the Karnataka State Forest Department for permission and support during field work (PS PCCF.WL.CR-38/2004-05). We thank Sameer Ali, Vishnu, and Lakshminarayan for their assistance during field investigations and Sudhira, Joby Joseph, and Sreekantha for valuable suggestions on acoustics.

Submitted by **K. V. GURURAJA** (e-mail: gururaj@ces.iisc.ernet.in), and **T. V. RAMACHANDRA**, Energy and Wetlands Research Group Centre for Ecological Sciences, Indian Institute of Science, Bangalore – 560 012, India.

PRHYNOHYAS VENULOSA (Rana Lechera). **LARVAL CANNIBALISM.** During the nights of 23 May and 4 June 2004, in a permanent pond in the Sierra de Perijá, Zulia state, Venezuela, we found several dead *Phrynohyas venulosa* tadpoles (Stage 39, Gosner 1960. Herpetologica 16:183–190) being consumed by many conspecific tadpoles of similar size. Larval cannibalism in hylid frogs has been previously reported for *Hyla rosenbergi* (Kluge 1981. Misc. Publ. Mus. Zool. Univ. Michigan 160:1–170) and *H. faber* (Sèrigo and Assêncio 1999. Herpetol. Rev. 30:162), and conspecific egg predation by tadpoles in *P. resinifictrix* (Schiesari et al. 2003. Copeia 2003:263–272). Although the natural history of *P. venulosa* has been studied (Zweifel 1964. Copeia 1964:201–208), cannibalism has not been recorded. This is the first report of cannibalism in *P. venulosa* tadpoles. Some tadpoles were reared through metamorphosis to assure the identity of the material; these were deposited in the Museo de Biología de la Universidad del Zulia (MBLUZ-A-0222).

Submitted by **EDWIN INFANTE RIVERO**, La Universidad del Zulia, Facultad Experimental de Ciencias, Museo de Biología de La Universidad del Zulia, Sección de Herpetología, Apartado Postal 526, Maracaibo 4011, Venezuela (e-mail: edwinfantembluz@hotmail.com); and **FERNANDO ROJAS-RUNJAIC**, Museo de Historia Natural La Salle, Sección de Herpetología, Apartado Postal 1930, Caracas 1010-A, Venezuela (e-mail: rojas_fernando@hotmail.com).

RANA CASCADAE (Cascades Frog). **TADPOLE PREDATION**. Observations on anuran tadpole predation by birds is becoming more common (Bolitho and Retallick 1996. Herpetol. Rev. 27:140–141; McAlpine et al. 2001. Herpetol. Rev. 32:183–184; Castanho 2001. Herpetol. Rev. 32:103, Crump and Vaira 1991. Herpetologica 47:316–321). Furthermore, corvids have been documented preying on anuran tadpoles (Beiswenger 1981. Copeia 1981:459–460). Here I report predation on tadpoles of *Rana cascadae* by the Clark's Nutcracker (*Nucifraga columbiana*), a small corvid, observed in the Trinity Alps Wilderness, Trinity County, California, USA (40°55'30"N, 122°52'56"W; elev. 2195 m). These events occurred within 20 minutes during observations on 8 Oct 2004, initiated at 1740 h. Two *N. columbiana* were observed perching in trees near a drying pond (5 cm depth and 2 m^2 surface area) containing a high concentration of *R. cascadae* and Pacific Treefrog (*Hyla regilla*) tadpoles and metamorphosed individuals. I observed the birds with binoculars from a distance of 15 m. Shortly after observations began, both *N. columbiana* flew to the pond and began probing their beaks into the water. Each *N. columbiana* successfully captured a single *R. cascadae* tadpole. Since *R. cascadae* are much larger than *H. regilla* tadpoles, I was confident of a positive identification of tadpole species. Each bird then flew back to the tree where initially observed and consumed the tadpoles. One bird returned to the pond four minutes later and seized three more *R. cascadae* tadpoles, this time consuming them at the pond's margin.

Nucifraga columbiana typically relies on cached conifer seeds as a main source of nutrition for winter survival and breeding (Vander Wall and Balda 1977. Ecol. Monogr. 47:89–111). During the short autumn season in sub-alpine environments, many lentic water bodies containing amphibian larvae become very shallow or dry completely. Drying lentic water bodies can create high concentrations of amphibian larvae that become available as a food resource to terrestrial predators at the littoral margin. *Rana cascadae* larvae, and possibly recent metamorphs, may provide an important nutrition subsidy for *N. columbiana* just prior to the onset of winter.

Submitted by **JUSTIN M. GARWOOD**, Department of Wildlife Management, Humboldt State University, Arcata, California 95521, USA and Redwood Sciences Laboratory, 1700 Bayview Drive, Arcata, California 95521, USA; e-mail: jg18@humboldt.edu.

SCINAX ACUMINATUS (Mato Grosso Snouted Treefrog). **PREDATION**. The hylid *Scinax acuminatus* is distributed in southern Mato Grosso and Mato Grosso do Sul states in Brazil, Paraguay, Bolivia, and northern Argentina (Frost 2002. Amphibian Species of the World: An Online Reference V2.21). Despite this extensive distribution, life history data for this species are scarce. On 15 Feb 2005 at 2015 h we found an adult *S. acuminatus* (37.74 mm SVL; 3.5 g) in the stomach of the colubrid snake *Leptodeira annulata* (750 mm SVL; 27.4 g) in a *Ficus* sp. in the Brazilian Pantanal, Nhumirim Ranch (18°59'S, 56°40'W), Mato Grosso do Sul State. After regurgitating the frog (deposited as CEUCH 3553 in Coleção Zoológica de Referência do Campus de Corumbá), the snake was measured and released. That night many individuals of this frog and snake were found active in the same *Ficus* tree and in the palm *Attalea phalerata*, suggesting that *S. acuminatus* might be commonly preyed upon by *L. annulata* in the Pantanal.

Submitted by **DRÁUZIO H. MORAIS** and **ROBSON W. ÁVILA** (e-mail: robsonavila@nin.ufms.br), Departamento de Ciências do Ambiente, Laboratório de Zoologia, Campus do Pantanal, Universidade Federal de Mato Grosso do Sul. Av. Rio Branco, 1270, Caixa Postal 252, CEP 79301-970. Corumbá, MS, Brazil.

TURTLES

ACTINEMYS MARMORATA (Western Pond Turtle). **NEONATES.** *Actinemys marmorata* historically ranged from Oregon to Mexico west of the Cascade–Sierra axis (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press,

Washington, D.C. 578 pp.; Jennings and Hayes 1994. California Dept. of Fish and Game, Rancho Cordova Final Report, Contract 8023, 260 pp.; Storer 1930. Univ. California Publ. Zool. 32:429–441). Populations of *A. marmorata* in California's San Joaquin Valley are declining and it is currently listed as a California Species of Special Concern (Jennings and Hayes, *op. cit.*). However, we know little about the natural history of this species, especially the neonatal stage. Here, I report dates and locations of neonatal *A. marmorata* captures.

I trapped turtles at five sites in the northern San Joaquin Valley, California, USA, near the town of Los Baños. Los Baños Creek and Mud Slough North were in the China Island Unit of the North Grasslands Wildlife Area and Field 26, Field 42, and the Wasteway were in the Volta Wildlife Area. During 2003, Los Baños Creek was trapped from 4 April and 31 May, Mud Slough North from 5 April – 17 June, Field 26 from 1 April – 24 May, Field 42 from 22 June – 22 July, and the Wasteway from 21 May – 10 August. I captured neonate *A. marmorata* in modified eel pot traps (Casazza et al. 2000. Herpetol. Rev. 31:91–92) set to survey for Giant Garter Snakes (*Thamnophis gigas*) with 50 mm openings on either end. I placed traps 10 m apart along banks and tied them to emergent vegetation or stakes and checked them daily. I batch marked all captured neonates by clipping two V-shaped notches in the marginal scutes on each side of the nuchal scute prior to releasing them at the site of capture. I used dial calipers to measure the mid-line carapace length of three initial captures.

Mid-line carapace length of the initial 3 turtles captured were 23.8, 26.7, and 27.5 mm with additional captures being of comparable size and within the size range given for hatchling *A. marmorata* (Buskirk 2002. Radiata 11:3–30). The shells of all hatchlings caught had not yet hardened, further indicating they had emerged from the nest that year (Ernst et al., *op. cit.*). Neonate capture dates are as follows: Los Baños Creek (12 [2 captures], 20, 23 [1 recapture] April); Mud Slough North (19 April, 11 May, 12 June); Field 26 (13, 15, 19, 20 [2 captures], 22, 24, 29 [2 captures] April, 1 [recapture], 14 May); Field 42 (5 June); the Wasteway (27 June). Additional species captured included Giant Garter Snakes, Common Gartersnakes (*Thamnophis sirtalis*), Common Kingsnakes (*Lampropeltis getula*), Gopher Snakes (*Pituophis catenifer*), Bullfrog adults and tadpoles (*Rana catesbeiana*), and various unidentified voles, birds, minnows, and aquatic insects.

Because *A. marmorata* is a California Species of Special Concern it is critical to understand its life history and population dynamics. Earliest captures dates for *A. marmorata* at one site in central California (Alameda Co.) are consistent with our findings (Buskirk, *op. cit.*). Jennings and Hayes (*op. cit.*) reported no recruitment in *A. marmorata* populations in California's Central Valley. However, later research reported young turtles were caught throughout the Central Valley of California suggesting recruitment in these populations (Germano and Bury 2001. Trans. West. Sect. Wildl. Soc. 37:22–36). Understanding the habitat requirements and fates of neonates will improve future assessments of the age structure and stability of Central Valley populations.

I thank C. Dickert for project coordination, J. Brown, J. Schmidt, J. Sloan, and C. Sousa for help with field work, and G. Dayton, J. Sloan, and two anonymous reviewers for valuable comments. Project support was provided by California Department of Fish and Game, Los Baños Wildlife Area, and the Grasslands Water District. Animals were handled under the authority of the California Endangered Species Act while I was employed with California Department of Fish and Game.

APALONE FEROX (Florida Softshell Turtle). **PREDATION.** During surveys for protected species at the site of a proposed development project in Lake County, Florida, USA, a series of burrows used by Burrowing Owls (*Athene cunicularia*) was located. Earlier in the season, one of the burrows had been used for nesting by the owls. On 4 October 2001 at 1500 h, the carcass of a hatchling *Apalone ferox* was located in the mouth of the nest burrow. The fresh carcass was missing its head, anterior right leg, left forefoot, internal organs, as well as a portion of the right anterior carapace. The rest of the carcass was intact. The maximum straight-line carapace length was 29.5 mm. The closest body of water to the burrow location was an ephemeral wetland, located ca. 600 m away, which was dry and vegetated with tall grass when the carcass was found. The closest permanent water sources were approximately 2.5 and 3.5 km away in opposite directions. The specimen (UF 141547) was deposited in the Florida Museum of Natural History, Gainesville, Florida.

Observations of owls consuming turtles are uncommon. Barn owls (*Tyto* sp.) prey upon juvenile Eastern Box Turtles, *Terrapene carolina* (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C.). In addition, Great Horned Owls (*Bubo virginianus*) reportedly capture hatchling Loggerhead Seaturtles (*Caretta caretta*) as they exit their nest (Toland 1991. Fla. Field Nat. 19: 117–119). Burrowing Owls are known to consume various species of insects, crabs, crayfish, frogs, toads, lizards, and snakes, small rodents, and birds (Bent 1961. Life Histories of North American Birds of Prey, Part two. Dover Publications, New York. 482 pp.). To our knowledge, this is the first documentation of predation by *A. cunicularia* on a turtle.

We thank Kenneth L. Krysko of the Florida Museum of Natural History for his assistance.

Submitted by **ANDREW D. WALDE** (e-mail: awalde@hotmail.com) and **RAYMOND A. SAUMURE**, Department of Natural Resource Sciences, McGill University, 21111 Lakeshore Road, Ste.-Anne-de-Bellevue, Québec, Canada, H9X 3V9.

GOPHERUS AGASSIZII (Desert Tortoise). **DIET**. On 23 August 2004, an adult female Desert Tortoise was observed foraging on the scat of the Black-Tailed Jackrabbit (*Lepis californicus*) in the western Mojave Desert northeast of Barstow, San Bernardino County, California, USA. The tortoise was observed to eat three pellets, though it is unknown how many were consumed prior to initiation of observations. At widely separated locations within our study site, two separate observations of tortoise feces containing entire *L. californicus* scats were discovered, suggesting different individuals in each case. One tortoise scat was found in mid-October 2004 and contained one entire rabbit pellet. Another scat

was found on 4 November 2004 at the entrance to a female tortoise's hibernation burrow. This scat was fresh and contained three rabbit pellets, along with coarse plant fibers, seeds, as well as sand and small gravel.

In addition to native and exotic vegetation, *Gopherus agassizii* individuals have been observed to consume bones, stones, and soil (Esque and Peters 1994. *In* Bury and Germano [eds.], Biology of North American Tortoises. pp.105–111. Nat. Biol. Surv., Fish Wildl. Res. 13. Washington, D.C.). Observations on Desert Tortoise foraging behaviors have also included bird feathers, mammal hairs, snake and lizard scales, arthropod parts (Hansen et al. 1976. Herpetologica 32:247–251), and scat from Desert Woodrats (*Neotoma lepida*), lizards, and other Desert Tortoises (Henen 2002. Chel. Cons. Biol. 4:319–329). Ingestion of these various other items is suspected to be important for mineral and nutrient supplementation. The scats of rabbit are known to be nutritious (WallisDeVries 1996. J. Appl. Ecol. 33:688–702). This latter study found that cattle ate rabbit feces because it was of equal nutritive value to the sparse winter grasses and that the cattle could consume the feces at a faster rate than the sparse grass. The Texas Tortoise (*Gopherus berlandieri*) has also been observed consuming rabbit droppings (Auffenberg and Weaver 1969. Bull. Florida State Mus. 13:141–203) indicating that consumption of rabbit feces by tortoises is not an isolated event. Thus, the fibrous rabbit pellet may act as a food source for the Desert Tortoise from which trace elements or nutrients may be obtained and, if fresh, a small amount of water.

An alternate explanation for the consumption of feces, as demonstrated in Common Iguanas (*Iguana iguana*), is that intra-specific coprophagy is important in the transfer and inoculation of unique gut microbial symbionts which assists in digestion (Troyer 1982. Science 216:540–542). Intra-specific coprophagy, typically juveniles eating adult feces, is a well-documented behavior in reptiles (Montanucci 1999. Herpetol. Rev. 30:221–222; Troyer 1982, *op. cit.*) and has been observed in many species of tortoises (Ernst and Barbour 1989. Turtles of the World. Smithsonian Institution Press. Washington, D.C.), including the Desert Tortoise (Lance and Morafka 2001. Herpetol. Monogr. 15:124–134; Henen 2003, *op. cit.*). It is assumed that a similar inoculation function is present for the Desert Tortoise. Inter-specific coprophagy may play a similar role as many species of tortoise worldwide have been observed to consume feces (Ernst and Barbour 1989, *op. cit.*). Congeners of the Desert Tortoise have been observed consuming feces including: Gopher Tortoises (*G. polyphemus*) eating fox and their own scat (Anderson and Herrington 1992. Herpetol. Rev. 23:59; Macdonald and Mushinsky 1988. Herpetologica 44:345–353); Texas Tortoises eating Collared Peccary (*Tayassu tajacu*) feces (Mares 1971. Texas J. Sci. 23:300–301) as well as rabbit droppings and their own feces (Auffenberg and Weaver 1969, *op. cit.*); and Desert Tortoises have been observed eating scat from Desert Woodrats, lizards, Collared Peccaries, and other Desert Tortoises (Henen 2002, *op. cit.*; Hart et al. 1992. Unpubl. report to Arizona Game and Fish Dept. and U.S. Bureau of Land Management, Phoenix). Many of these observations involve the consumption of other herbivores' scats, which might aid in the transfer of gut microflora such as bacteria and fungi. Our observation of a Desert Tortoise eating the scat of another desert herbivore might provide the Desert Tortoise with nutrients and might also provide the tortoise with a unique gut microflora. To our knowledge these are the first reports of adult Desert Tortoises eating scat of *L. californicus*.

Funding and field support for this project was provided by ERDC/CERL. In addition, we thank Mickey Quillman, DPW Environmental, Ft. Irwin for providing additional logistical and financial support. Research was conducted under USFWS recovery permit TE066452-1 and CAFG Memorandum of Understanding for Scientific Collecting Permit 802005-03.

GOPHERUS POLYPHEMUS (Gopher Tortoise). **COYOTE PREDATION.** *Gopherus polyphemus* is listed as a species of special concern by the state of Florida (Florida Wildlife Code Chap. 39 F.A.C.), and as a threatened species by the Florida Committee on Rare and Endangered Plants and Animals (Moler 1992. Rare and Endangered Biota of Florida: Volume III, Reptiles and Amphibians. University Press of Florida, Gainesville, Florida. 291 pp.). Coyotes (*Canis latrans*) are invasive to Florida with ranges that are expanding within the state (Schmitz and Brown 1994. An Assessment of Invasive Non-Indigenous Species in Florida's Public Lands. Florida Dept. Environmental Protection. Tallahassee, Florida. 283 pp.; Wooding and Hardinsky 1990. Florida Field Nat. 18:12–14), including the southeastern coast (Cunningham and Dunford 1970. Quart. J. Florida Acad. Sci. 33:279–280; Brady 1983. Florida Field Nat. 11:40–41; Hill et al. 1987. Wildl. Soc. Bull. 15:521–524; Wooding and Hardinsky, *op. cit.*). We report here evidence of Coyote predation on Gopher Tortoise hatchlings in southeastern coastal Florida.

Passive tracking index data used to monitor both exotic and native species on public lands (Engeman et al. 2001. Environ. Cons. 28:235–240) indicated an increasing presence of Coyotes on state and county public lands in the Palm Beach to Port St. Lucie areas (Engeman, unpubl. data), prompting us to opportunistically examine Coyote scats for evidence of Gopher Tortoise predation. On 3 April 2004, one of us (JAM) collected a Coyote scat with Gopher Tortoise remains from a path in a pine flatwoods greenway in the Abacoa development of Jupiter, Florida. The dried scat was 9 cm long and the gular projection of the plastron of a 2–3 yr old Gopher Tortoise was clearly visible, along with mammal fur, rodent bones, and grasshopper fragments. Hatchlings might be more vulnerable to predation than juveniles, but less noticeable in casual observation of scats. Efforts at the time to conduct larger surveys for evidence of Gopher Tortoises in coyote scats were made impossible by hurricanes Frances and Jeanne. Coyote predation on Gopher Tortoises is of concern because predation is a critical threat to endangered or locally rare species (Hecht and Nickerson 1999. Endangered Species Update 16:114–118), and predation losses can further stress populations already impacted by habitat loss and altered predator communities (Reynolds and Tapper 1996. Mammal Rev. 26:127–156), both of which apply to Gopher Tortoises in Florida.

KINOSTERNON INTEGRUM (Mexican Mud Turtle). **SIZE.** *Kinosternon integrum* is one of the largest species in the genus (Pritchard and Trebau 1984. The Turtles of Venezuela. SSAR. 466 pp.) and males obtain larger sizes than females. The largest specimens reported in the literature were 202 mm carapace length (CL) (Ernst and Barbour 1989. Turtles of the World. Smithsonian Institution Press. 313 pp.) and 210 mm CL (Iverson et al. 1998. Cat. Amer. Amphib. Rept. 652:1–6). We found two males exceeding 210 mm CL in the municipality of Tonatico, Estado de México, México (18°45'04"N, 99°37'35"W) in April 2004. The first male was 223 mm CL with a mass of 662.9 g, and the second 220 mm CL and 810 g. This apparently represents the largest size (CL) reported to date for males of this species.

TRACHEMYS GAIGEAE (Big Bend Slider). **REPRODUCTIVE CHARACTERISTICS.** Relatively little information has been published on reproduction in *T. gaigeae* (see review by Stuart and Ernst. 2004. Cat. Amer. Amphib. Rept. 787:1–6). Herein we provide descriptive statistics and other data for the subspecies *T. g. gaigeae* (following taxonomy of Seidel 2002. J. Herpetol. 36:285–292) obtained during field studies in the Rio Grande Valley, southern Socorro County, New Mexico, USA in 1996–1998. Collection methodology and locations were previously discussed by Stuart and Painter (2002. Bull. Maryland Herpetol. Soc. 38:15–22). Mensural data are presented as: mean ± standard deviation, range.

Twelve adult females (maximum straight-line carapace length [CL] = 242.2 mm ± 11.9, 228–266 mm; maximum straight-line plastron length [PL] = 228.3 mm ± 11.1, 213.5–247 mm; pre-oviposition mass = 1890.1 g ± 281.4, 1538–2364 g), captured in aquatic traps, were identified as gravid with shelled eggs based on abdominal palpation. Dates of collection were between 19 May and 11 July; no female captured before or after this period showed evidence of bearing shelled eggs. All 12 females were induced to oviposit within 24–48 h of capture by injection of oxytocin (Ewert and Legler 1978. Herpetologica 34:314–318) and were judged to be spent (devoid of shelled eggs) via abdominal palpation over a several day period post-oviposition. Eggs were incubated in moist vermiculite at 28–30°C in the laboratory, and hatchlings were retained alive for up to 12 months post-hatching.

Number of eggs per clutch (N = 12) averaged 15.4 ± 4.9, 6–22. Previous reports of clutch size in *T. g. gaigeae* ranged from 6 to 29 (reviewed by Morjan and Stuart 2001. Southwest. Nat. 46:230–234). Eggs (N = 170) were measured within 24 h after laying. Egg length averaged 35.0 mm ± 1.3, 31.6–37.7 mm; and width averaged 22.5 mm ± 0.9, 20.1–24.6 mm. Individual egg mass (N = 147, from 10 of the 12 clutches) averaged 10.7 g ± 1.1, 8.5–13.0 g.

Incubation period in the laboratory for 11 clutches averaged 60.8 days ± 2.4, 57–64 days, and hatching success rate was ca. 72%. Hatchlings (N = 123) were measured within one month after hatching: CL averaged 29.0 mm ± 1.4, 25.2–32.7 mm; PL averaged 27.4 mm ± 1.2, 24.1–30.6 mm; and mass averaged 6.0 g ± 0.8, 4.3–7.7 g. As noted by Morjan and Stuart (2001, *op. cit.*), the hatchling color pattern was similar to that of adults, although the reticulate pattern on the carapace was much more densely arranged, and the olive carapace and yellowish plastral colors were much paler and duller than in adults.

In 10 clutches, mean egg mass was significantly correlated with means of egg length ($r^2 = 0.77$, $F = 27.0$, $p < 0.001$), egg width ($r^2 = 0.84$, $F = 42.9$, $p < 0.001$), hatchling CL ($r^2 = 0.65$, $F = 15.0$, $p < 0.005$), and hatchling mass ($r^2 = 0.79$, $F = 30.9$, $p < 0.001$). Mean length and width of eggs were significantly correlated with mean hatchling CL ($r^2 = 0.56$, $F = 11.4$, $p < 0.01$; and $r^2 = 0.52$, $F = 9.8$, $p = 0.01$, respectively). Female CL and pre-oviposition mass were not significantly correlated with length, width, or mass of eggs; clutch mass or size; or hatchling CL or mass (r^2 values < 0.26, $p > 0.13$), possibly because of the small sample size. However, extensive variation in these reproductive characteristics has been observed in better-studied species of slider such as *T. scripta* in the U.S. (e.g., Tucker et al. 1998. J. Herpetol. 32:515–526).

Egg mass index (EMI; mean individual egg mass × 100/spent female mass) and relative clutch mass (RCM; clutch mass/spent female mass) were calculated for 10 females and their clutches. EMI averaged 0.65 ± 0.10, 0.55–0.86, and RCM averaged 0.10 ± 0.02, 0.05–0.14. The mean EMI for *T. g. gaigeae* fell between ratios reported for *Trachemys* spp. from the central U.S. (0.95) and Central America (0.41–0.49), whereas the mean RCM was comparable to that of *T. scripta* in the central U.S. (0.10) but lower than the ratio for *T. venusta* in Costa Rica (0.14) (Moll and Moll 1990. *In* J. W. Gibbons [ed.], Life History and Ecology of the Slider Turtle, pp. 152–161. Smithson. Instit. Press, Washington, D.C.; Moll 1994. Chelon. Conserv. Biol. 1:107–116). In terms of EMI, *T. g. gaigeae* appears to be intermediate between temperate and tropical populations of *Trachemys* spp.

Our data, although derived from a small number of gravid females and their offspring, suggest that *T. g. gaigeae* is similar in its reproductive characteristics to other species of *Trachemys*. We thank K. A. Buhlmann, J. D. Congdon, and J. M. Legler for comments, and J. B. M. Miyashiro for assistance. Fieldwork was funded in part by the New Mexico Department of Game and Fish, Share with Wildlife Program.

Submitted by **JAMES N. STUART** (e-mail: JStuart@state.nm.us) and **CHARLES W. PAINTER**, New Mexico Department of Game and Fish, Conservation Services Division, Santa Fe, New Mexico 87504-5112, USA.

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). **REPRODUCTION**. The natural range of *Trachemys scripta elegans* extends from northern Illinois to the Gulf of Mexico, USA (Gibbons and Zug 1990. Life History and Ecology of the Slider Turtle. Smithsonian Books. 384 pp.). *T. scripta elegans* has been introduced and successfully reproduces in California (Lever 2003. Naturalized Reptiles and Amphibians of the World. Oxford University Press. 288 pp.). The northernmost known occurrence of *T. scripta elegans* in California occurs in Contra Costa Co., south of San Francisco (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, Houghton Mifflin Co., Boston, Massachusetts. 533 pp.). Here, I report the first occurrences and breeding success of *T. scripta elegans* in Marin County, California. This apparently represents the most northern occurrence of a breeding population of this non-native species in California to date. Assisted by two biologists from Garcia and Associates, I conducted a Western Pond Turtle (*Actinemys marmorata*) population study from April to August 2003 in the Mount Tamalpais Watershed, Marin Municipal Water District, Marin County. During that study, we captured numerous reproductive *T. s. elegans* males and females (palpation of eggs) at two lakes. We also captured sub-adults, juveniles, and five hatchlings. Juveniles and hatchlings caught were likely the offspring of adults released in the lakes, since juveniles under 10 cm in length are not legally available in the pet trade in the United States.

CROCODYLIA

ALLIGATOR MISSIPPIENSIS (American Alligator). **FEEDING.** *Alligator missippiensis* is a large, abundant carnivore in marshes and swamps of the southeastern United States. Small *A. missippiensis* (< 1.5 m TL) eat what is locally available, consuming primarily invertebrates, small fish, and amphibians. As *A. missippiensis* grow larger, they eat larger fish and amphibians, snakes, turtles, birds, mammals, and shellfish (Mazzotti and Brandt 1994. *In* Davis and Ogden [eds.], Everglades: The Ecosystem and its Restoration, pp. 485–505. St. Lucie Press, Delray Beach, Florida). Reports of exotic snakes in Everglades National Park (ENP) include increased sightings of Burmese Pythons (*Python molurus bivittatus*; Snow and Oberhofer 2004. http://www2.nature.nps.gov/YearinReview/02_B.html). Sources of mortality of pythons include motor vehicles, mowing equipment, fire, and possibly alligators. Here, we confirm the latter with a report of an *A. missippiensis* feeding on a *P. m. bivittatus* (Fig. 1).

At 1015 h on 7 June 2005, an adult (ca. 2.4 m) *A. missippiensis* emerged from a well-used alligator trail into a box culvert pool along the south side of the Main Park Road (SR 9336) of ENP (25°24'13.1"N, 80°36'34.1"W, datum: NAD83; elev. ca. 1 m). This box culvert is 1.85 km W of the main entrance (fee booth) to the ENP. When first observed, the alligator had a subadult (ca. 2.6 m TL) *P. m. bivittatus* in its jaws. The alligator held the python just behind the head, and the snake was wrapped around the body of the alligator. The python's head was above water and the snake was obviously alive, with its tongue flicking. By 1215 h, the python was no longer wrapped around the alligator; the snake's head was submerged and its body appeared limp. At 1310 h, the alligator began to swallow the python, throwing its head back, "chomping," with lengthy rests in between. By 1410 h, the alligator had ca. 1.3 m of python trailing from its mouth, having swallowed the snake whole, head first. No further observations were made until 1507 h, at which time there was still ca. 1 m of visible snake. At 1556 h, the alligator continued to toss its head and "chomp," then rest with its head out of the water on the bank. At 1601 h, the *A. missippiensis* made another attempt to swallow more python, and then rested. At 1627 h, the alligator re-engaged in several bouts of swallowing with little progress. By 1642 h, the *A. missippiensis* had made some progress, with about 0.6 m of the snake remaining to be swallowed. At 1716 h, the alligator rested for 30 min with its head out of water on the bank edge. This was followed by more swallowing attempts and resting. Observations ceased at 1938 h with ca. 0.6 m of python still hanging out of the alligator's mouth.

The culvert was visited 5 times between 0715 h and 1715 h the following day. No observations of python or alligator were made. On 9 June 2005 at 0715 h, the same alligator was observed in the north side culvert pool with about 0.1 m of python's tail hanging out of its mouth (Fig. 1). The alligator left the culvert pool by 0945 h. This alligator was seen again at the culvert at 1445 h with no snake parts showing. The alligator has not been seen in more than 60 visits to that culvert pool since.

This is not the first observation of alligators encountering pythons in ENP. On 5 January 2003, a park visitor reported an alligator estimated to be over 2 m TL and a python estimated to be over 3 m TL battled for more than 24 h at Anhinga Trail. Although the alligator appeared to have subdued the python, the snake broke free and swam off into the marsh. On 3 February 2004, a small group of tourists at Pa-hay-okee Overlook reported that a large python (reported at over 6 m TL) had wrapped itself around an adult alligator (reported as 3.5 m TL). Photographs of the encounter suggest that the python was closer to 4 m TL and the alligator 2.5 m TL. The alligator had been reported to grab the python in its mouth and swim away.

The difficulty with which *A. missippiensis* had swallowing the python in the encounter we describe suggests that a limit to snake prey size exists. Spectacled Caiman (*Caiman crocodiles*) are re-

FIG. 1. American Alligator eating Burmese Python in Everglades National Park, Florida.

ported to kill Green Anacondas (*Eunectes murinus*) in the Venezuelan Llanos. Smaller snakes were eaten, but larger ones were not consumed (Rivas et al. 1999. Herpetol. Rev. 30:101). Rivas et al. (*op. cit.*, 1999) also reported that anaconda predation on caimans often occurs.

That three alligator-python battles have been reported over a 29-month period in ENP indicates either that these interactions are common or easily observed. More data on the ecology of Burmese Pythons in ENP is needed to evaluate extent and importance of interactions between these two species.

We thank Bill McCreary, Mark Grissom, and John C. Benjamin Jr. for their observations and photographs of the January 2003 encounter; and Donna Mercier for her sharp-eyed observation and Mike Mercier for his excellent photographs of the February 2004 encounter.

Submitted by **RAY W. SNOW** (e-mail: skip_snow@nps.gov) and **LORI OBERHOFER** (e-mail: lori_oberhofer@nps.gov), South Florida Natural Resources Center, Everglades National Park, 40001 State Road 9336, Homestead, Florida 33034, USA; and **FRANK J. MAZZOTTI**, Department Wildlife Ecology and Conservation, Fort Lauderdale Research and Education Center, University of Florida, 3205 College Avenue, Davie, Florida 33314, USA (e-mail: fjma@ufl.edu).

PALEOSUCHUS PALPEBROSUS (Dwarf Caiman). **NESTING.** *Paleosuchus palpebrosus* is widely distributed in Brazil, but its reproductive biology remains poorly documented (Magnusson 1992. Cat. Am. Amphib. Rept. 554.1–554.2). Here, we add observations of *P. palpebrosus* nesting in northern Brazil to the limited reproductive data on this species.

We searched for nests around Cururu Lake, near the Solimões River (03°34'30.4"S, 60°40'03.3"W, datum: WGS84; elev. 80 m), State of Amazonas in November–December 2001 and 2002. We found two *P. palpebrosus* nests in the forest around lake. Nests were found in the forest seasonally flooded by the lake and small streams, at distances of 15–20 m from water, and were built from decaying leaves and twigs.

One nest, which was intact, was 55 cm high, 108 cm long, and 70 cm wide. We could not obtain precise dimensions on the second nest because a predator had disturbed it; pieces of eggshells were scattered about. The intact nest had 15 eggs, and we measured the length, width, and weight of 8 eggs. Mean egg length was 61.1 cm (SD = 2.0), mean egg width was 38.1 cm (SD = 1.5), and mean egg mass was 56.4 g (SD = 3.6). We captured a female *P. palpebrosus* (69.0 cm SVL, 8.0 kg) near the intact nest (Fig. 1).

Nests of this species have been reported from Colombia and Surinam (Medem 1981. Los Crocodylia de Sur America. Vol. 1. Colciencias, Bogota, Colombia. 354 pp.; Medem 1983. Los Crocodylia de Sur America. Vol. 2. Colciencias, Bogota, Colombia. 270 pp.), but this is the first nest reported from the Amazon region of Brazil. Nest structure and material was generally similar to nests found elsewhere, though some nests have also been recorded on floating vegetation mats in Surinam (Medem 1981, *op. cit.*). Clutch size in all three areas (13–15/nest) is similar, and the size of *P. palpebrosus* eggs reported by Medem (1981, *op. cit.*) is similar to the size of eggs we found.

FIG. 1. *Paleosuchus palpebrosus* nest in foreground with female *P. palpebrosus* (69 cm SVL) in background.

We thank for Dete, Peruano, Dunga, Teixeirinha, and João Paulo for help in the field, and William Magnusson for reviewing the note.

RHYNCHOCEPHALIA

SPHENODON PUNCTATUS (Common Tuatara). **OPPORTUNISTIC PREDATION**. *Sphenodon punctatus* are opportunistic visual predators. In the wild, they feed primarily on invertebrates including weta (Orthoptera), beetles (Coleoptera), and isopods (*Oniscus* spp.) (Walls 1981. New Zealand J. Ecol. 4:89–97). Accounts also exist of tuatara feeding on vertebrate prey, including skinks (*Oligosoma* spp.), geckos (*Hoplodactylus* spp.), and frogs (*Leiopelma hamiltoni*) (Brown 1994. New Zealand J. Zool. 21:425–430). Adult *S. punctatus* occasionally feed on Fairy Prion (*Pachyptila turtur*) eggs, chicks (Wright 1961. Notornis 9:133) and adults (Walls 1978. New Zealand J. Ecol. 1:91–98), but this is not surprising as these colonial ground-nesting birds occur in large numbers, often sharing burrows with tuatara (Newman 1987. Herpetologica 43:336–344). However, no accounts exist of *S. punctatus* feeding on passerine birds. Hence, we report an observation of *S. punctatus* predation on a House Sparrow, *Passer domesticus*.

At ca. 1000 h on 23 March 2005, we encountered an adult (ca. 250 cm SVL) male *S. punctatus* with a *P. domesticus* in its mouth on the northeastern side of Stephens Island (Marlborough Sounds, New Zealand, 40°40'S, 174°00'E, datum: NZGD49; ca. elev. 215 m). The event occurred under the dense undergrowth directly beside a small shed that is ca. 5 m from the sliding glass door of one of the three houses on the island. The head had already been consumed, but the sparrow was clearly identifiable (Fig. 1). The sparrow was difficult to age due to it already having been partially consumed; however, based on feather and leg development, it was either an older juvenile or an adult (i.e., flight capable). After ca. 2 h, the *S. punctatus* managed to eat the sparrow whole, by very

FIG. 1. Adult male Common Tuatara (*Sphenodon punctatus*) in the process of consuming a House Sparrow (*Passer domesticus*) on Stephens Island, New Zealand.

slowly chewing down the length of the bird's body.

This is the first report of *S. punctatus* feeding on a passerine bird. It is unknown what enabled the capture of this sparrow, as passerine birds are not known to be a primary prey item for *S. punctatus*. As the incident occurred within 3 m of a glass door, the sparrow may have been captured opportunistically after having been stunned as a result of flying into the glass and subsequently attracting the tuatara's attention. However, if the bird had recently fledged, its inexperience could have enabled its capture. We expect that the ecology of House Sparrows, an introduced species in New Zealand, makes them only occasional prey for *S. punctatus*.

We thank C. Allen and J. de Vries for assistance on Stephens Island, and B. Bell, H. Miller, and D. Chapple for providing comments on the draft. Our research was conducted with New Zealand Department of Conservation approval.

Submitted by **JENNIFER A. MOORE**, Allan Wilson Centre for Molecular Ecology and Evolution, Victoria University of Wellington, P.O. Box 600, Wellington, New Zealand (e-mail: Jennifer.Moore@vuw.ac.nz); and **STEPHANIE S. GODFREY**, Flinders University of South Australia, Bedford Park, Adelaide, Australia.

LACERTILIA

AMEIVA AMEIVA (Giant Ameiva). **PREDATION.** *Ameiva ameiva* may be the most studied Brazilian lizard; selected aspects of its ecology, e.g., reproduction (Colli 1991. Copeia 1991:1002–1012) and diet and thermal ecology (Vitt and Colli 1994. Can. J. Zool. 72:1986–2008) are well known. Although *A. ameiva* is known to prey on other lizards and amphibians (Pianka and Vitt 2003. Lizards. University of California Press, Berkeley. 346 pp.), relatively few data on its predators exist, such as snakes (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150), mammals (Yensen and Tarifa 2003. Mammalian Species 727:1–8) and introduced predators (Henderson 1992. Caribb. J. Sci. 28:1–10). Hence, we add to the limited data on *A. ameiva* predators with observations of *Pseudoboa* (snake) predation on *A. ameiva* from the Pantanal, Corumbá municipallity, Mato Grosso do Sul State, Brazil.

On 04 April 2001, we received a dead juvenile female *Pseudoboa nigra* (396 mm SVL) killed by locals from an urban area of Corumbá (18°58'48"S, 57°39'18"W, datum: WGS84; elev. 90 m); dissection revealed one hand (12.8 mm) and a tail (66.6 mm) of a subadult *A. ameiva* in the stomach. Dry forest dominated by Fabaceae, Euphorbiaceae, Apocynaceae, Rubiaceae, and Sapindaceae surrounds the area; *A. ameiva* is common in the vicinity (pers. obs.).

On 20 June 2001, we captured a juvenile (336 mm SVL) male *Pseudoboa neuwiedii* in a 50-m set of four 106-liter pitfall traps with drift-fences placed on Santa Cruz Hill (19°24'49"S, 57°22'47"W, datum: WGS84; elev. 800 m). Semi-deciduous forest dominated by Caesalpiniaceae, Euphorbiaceae, Mimosaceae, Rutaceae, and Bignoniaceae characterizes the area. Dissection revealed a subadult (148 mm tail length only) female *A. ameiva* in stomach.

We recorded a third instance of predation on *A. ameiva* when we received an adult female *Pseudoboa haasi* (1092 mm SVL) killed by local workers in the Pantanal region called Nhecolândia (18°59'S, 56°40'W; datum: WGS84; elev. 98 m). The region is characterized by a matrix of different Cerrado habitats in which Bignoniaceae, Arecaceae, and Malpighiaceae are dominant in the vegetation. Dissection revealed a foot (29.3 mm), shed skin, and pieces of tail of an adult *A. ameiva* in the stomach.

Previous studies on snakes report that *Pseudoboa* prey on lizards (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150; Strussmann and Sazima 1993. Stud. Neotrop. Fauna Environ. 28:157–168). Our findings suggest that these snakes may be important predators of actively foraging lizards, such as *A. ameiva*. The three *Pseudoboa* specimens (CEUCH 874, 904, and 3550) and their respective stomach contents are deposited in the zoological reference collection, Laboratory of Zoology, Campus of Corumbá, Universidade Federal de Mato Grosso do Sul (UFMS). We thank Marc P. Hayes for comments and Mineração Corumbaense Reunidas for logistical support.

***AMPHISBAENA DARWINII DARWINII*.** (NCN). **REPRODUCTION.** The maximum clutch size reported for *Amphisbaena d. darwinii* is three eggs (Cei 1993. Mus. Reg. Sci. Nat. Torino, Monograf. 14:1–949; Achaval and Olmos 2003. Anfibios y Reptiles del Uruguay. 2nd Edición corregida y aumentada. Graphis, Impresora, Montevideo, Uruguay. 136 pp.). Here, we report a larger clutch size from southern Uruguay.

Diego Nuñez collected a clutch of four *A. d. darwinii* eggs at Avenida de los Pinos 2787, Colonia Nicolich, Ruta 102, km 23.2, Departamento Canelones (34°48'55"S, 56°01'13"W, datum: YACAR; elev. 27 m) on 30 December 2002. The leathery eggs were found within an unoccupied anthill in grassland habitat. The four eggs had mean dimensions of 24.7 mm × 13.0 mm, ranges: 24.0–25.0 × 13.0–15.0 mm). One egg was broken during manipulation; the other three eggs were incubated. Three hatchlings were born, two on 25 January 2003 (total length = 68 mm, mass = 0.73 g; total length = 85 mm; mass = 0.90 g), the third one day later (total length = 74 mm; mass = 0.67 g).

The four eggs and two dead hatchlings were deposited in the Colección Zoología Vertebrados, Reptiles (ZVC-R), Facultad de Ciencias, Montevideo as ZVC-R 6080. We thank Diego Nuñez for specimen data.

CNEMASPIS **(Oriental Dwarf Geckos). COMMUNAL OVIPOSITION.** Communal egg-laying is widely reported among squamate reptiles, including many geckos (e.g., Krysko et al. 2003. Amphibia-Reptilia 24:390–396; Oda 2004. Acta Amazonica 34:331–332). Among South Asian gekkonids, selected species in several genera show this behavior (e.g., Bauer and Das 2000. J. South Asian Nat. Hist. 5:25–35; Das 2003. A Photographic Guide to Snakes and Other Reptiles of India. New Holland Publishers, London. 144 pp.; Khan and Tasnim 1990. Herpetologica 42:146–148), including some members of the genus *Cnemaspis*. In *Cnemaspis,* three species are known to exhibit communal oviposition; *C. kandiana* from Sri Lanka (Deraniyagala 1953. A Colored Atlas of Some Vertebrates from Ceylon, Vol. 2, Tetrapod Reptilia. The Ceylon Government Press, Colombo. 121 pp.), *C. indica* from the Western Ghats of India (Bhupathy and Nikon 2002. J. Bombay Nat. Hist. Soc. 99:330–332), and *C. baueri* from Peninsular Malaysia (Das and Grismer 2003. Herpetologica 59:544–552). Here, we add to previous reports of communal oviposition in *Cnemaspis* with observations from the Western Ghats of southern India.

On 22 September 2004, SB observed three sites with clusters of eggs of *Cnemaspis cf. indraneildasii* in Anashi National Park (ANP). All sites were on partly moss-covered bridge walls above dry or flowing streams under the road connecting Anashi village and Anashi Nature Camp. Eggs were white to off-white in color, translucent, longer than wide (oval), flattened at their wall-attached end, and generally represented three categories; unhatched, recently hatched and previously hatched. Recently hatched eggs typically had only their apical ends broken with most of the egg shell remaining, whereas previously hatched eggs only had basal fragments of the shell attached to the wall. Site 1 (15°00'08"N, 74°13'39"E, datum: WGS84; elev. 540 m) had two clutches: 3 and 2 unhatched eggs within an area 15 cm in diameter with one isolated, recently hatched egg on either side. One unhatched egg was 5.3 mm wide; during measurement, this egg cracked (hence the length was unrecorded) whereupon an apparently healthy fully developed *C. cf. indraneildasii* (12.2 mm SVL, 13.2 mm tail) immediately emerged. At least 12 previously hatched eggs were also located near these unhatched eggs. An adult *C. cf. indraneildasii* and a juvenile *Hemidactylus prashadi* were noticed within 0.5 m and 0.8 m, respectively, on the same wall. Site 2 (15°00'06"N, 74°13'38"E; elev. 540 m) had 3 clutches of 2 recently hatched eggs. Below these eggs were 7 unhatched eggs (1 isolated egg and 3 clutches of 2). At least 10 previously hatched eggs were also located near these eggs. Site 3 (15°00'06"N, 74°13'31"E; elev. 540 m) had 3 separate aggregations of eggs. One aggregation had 3 unhatched eggs (1 isolated egg and a clutch of 2) with another clutch of 2 recently hatched eggs below them. Impressions of 2 previously hatched eggs were also present. An adult *C. cf. indraneildasii* was observed within 0.6 m of this cluster. The second aggregation had 4 unhatched eggs (2 single eggs and 1 clutch of 2). Remains of 17 previously hatched eggs were also present near these eggs. The third aggregation had 7 unhatched eggs (5 single eggs in lower right and 1 clutch of 2 in lower right of Fig. 1). The remains of 51 previously hatched eggs were also located all around the unhatched eggs (see Fig. 1). The distances between different categories of eggs were not recorded, but at all 3 sites, eggs were located within a ca. 1 m circle diameter. Egg(s) presumed to represent separate clutches were always laid in distinct clusters with the overall dispersion within a cluster as in Fig. 1. For previously hatched eggs, it was impossible to obtain accurate counts of clutch size as only their basal impressions were left and new eggs were frequently laid over older ones. Isolated egg groups (1–2 eggs) were rarely observed (N = 3) in other parts of ANP.

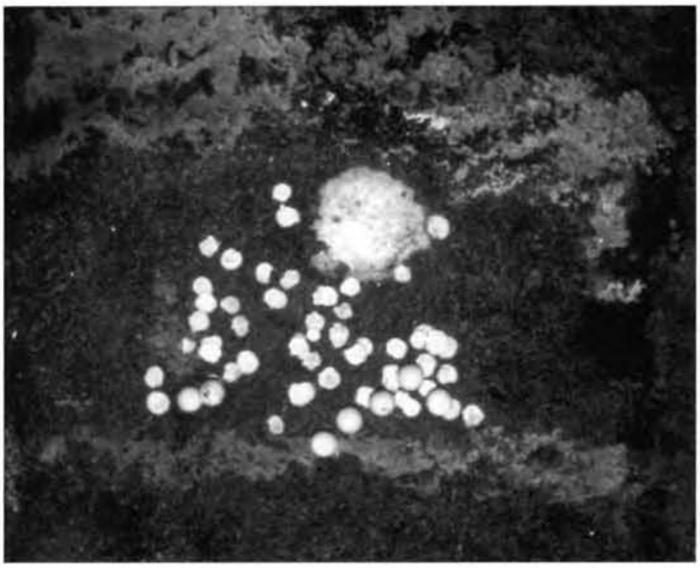

FIG. 1. Egg-laying of *Cnemaspis cf. indraneildasii* in Anashi National Park, Karnataka, India.

While studying reptiles in the Sengaltheri area of Kalakkad-Mundanthurai Tiger Reserve (KMTR), Tamil Nadu Forest, NMI observed aggregations *Cnemaspis* eggs. NMI located several *Cnemaspis* egg clusters (2–6 eggs) primarily in leaf litter, decaying logs, on the underside of tree bark, and under small stones during quadrat sampling. However, our description here refers to a site (08°31'45"N, 77°26'39"E; elev. 980 m) that harbored the largest aggregation of *Cnemaspis* eggs recorded from KMTR over the interval 1998–2000. The site was a 10-m wide rocky formation in a dense tree and canopy cover of mixed evergreen forest with minimal undergrowth. Except for ca. 2 months annually, the proximity of the Manimuttar River (15 m away) saturates the substrate. This site was ca. 1.5 m above ground in a narrow (ca. 1.5 cm wide) crevice due to one rock (ca. 1.5 m × 1 m × 2.5 m) sitting on a larger rock. Though the site is humid year-round, the environment in the crevice was not particularly moist. At least 50 unhatched and > 25 hatched eggs were recorded from this site. The area of visibility into the crevice was lined with eggs. Eggs were similar to those observed at ANP; other than *Cnemaspis*, no geckos recorded from KMTR (Ishwar et al. 2001. Current Sci. 80:413–418;

Murthy 1992. Rec. Zool. Surv. India 91:161–168) are likely to have similar-sized eggs. Only unhatched and previously hatched eggs were observed. Eggs seemed tightly packed into the crevice without obvious pattern, and several shell fragments were seen at the base of the crevice. *Cnemaspis* hatchlings observed in the nest eluded capture as they fled into the crevice when pursued. Three *Cnemaspis* species (*C. indica, C. ornata,* and *C. jerdoni*) were recorded in the vicinity with *C. indica* being most abundant.

Egg-laying was not observed, but oviposition by more than one individual is undoubtedly responsible for the large egg aggregations we describe (see Ananjeva and Orlov 1995. Russian J. Herpetol. 2:142–147; Bhupathy and Nikon, *op. cit.*). Moreover, the nest site at KMTR may be used by more than one species of *Cnemaspis* (see Krysko et al., *op. cit.*). *Cnemaspis* reproductive ecology is currently poorly described, but communal nesting in the genus may be more common than recorded (SB, NMI, unpubl. data from other areas). Hence, comparative information on the degree of site fidelity, frequency of multiple clutching, incubation time, and breeding season length will be needed to interpret the ecological and evolutionary context of oviposition aggregations.

The Karnataka and Tamil Nadu Forest Departments provided permits; K. Shanker, J. Krishnaswamy, the Ashoka Trust for Research in Ecology and the Environment, the U.S. Fish and Wildlife Service, and the Wildlife Institute of India provided logistic support. We thank M. P. Hayes and S. Pawar for comments and R. Somewara for the record of *C. kandiana* communal oviposition.

CTENOSAURA MELANOSTERNA (Black-chested Ctenosaur). **PREDATION.** At 1525 h on 19 July 2005, we saw a large (31.6 cm SVL, 51.5 cm tail, 996 g) *C. melanosterna* fall 4–8 m from the forest canopy on the island of Cayo Menor in the Cayos Cochinos (Islas de la Bahia, Honduras; 16°10'20"N, 86°30'10"W, datum: WGS84 ; elev. 8 m); a female *Boa constrictor* (133 cm SVL, 15.7 cm tail, 1267 g) was constricting the lizard. From the time the lizard and snake hit the ground, we could see no muscular activity in the lizard (including no obvious signs of respiration). The snake constricted the lizard for 34 min, then released the lizard and remained loosely coiled around it (and essentially motionless) for another 95 min. The snake then began to ingest the lizard, successfully swallowing the head and neck within 9 min. The snake then stopped, and again remained motionless. After 49 min, we placed the snake and lizard in a cloth bag and transported them to the lab. We placed both animals in a plastic storage bin (75 x 40 x 40 cm), hoping that the snake would finish eating the lizard. At 0800 h the next day, the snake and still unresponsive lizard were on opposite sides of the bin. At 1300 h the same day, we returned to the lab to find the snake on one side of the bin and the lizard alive and alert on the other. The lizard had been unresponsive for at least 21 h. We released the lizard at the point of capture the next day, whereupon it gave many aggressive head-bob displays before walking into the forest with no apparent ill effects.

Besides the observed predation attempt, we have found two adult female *B. constrictor* on Cayo Menor containing adult *C. melanosterna* (> 25 cm SVL). One female boa (117 cm SVL, 1661 g including prey) partially regurgitated a large *C. melanosterna*; the snake subsequently died in captivity. The other female (205 cm SVL, 5300 g including prey), discovered on 20 August 2004, contained a *C. melanosterna* (determined by palpation), and this snake subsequently was recaptured in good condition on 16 July 2005. These observations indicate that *C. melanosterna* might represent important prey for the insular boas. *Ctenosaura melanosterna* is known only from the Cayos Cochinos and Aguan Valley (Departamento de Yoro) in Honduras (Buckley and Axtell 1997. Copeia 1997:138–150). Little is known of *C. melanosterna* ecology, and although *B. constrictor* predation on adult *C. pectinata* has been recorded (Lemos-Espinal and Ballinger 1994. Herpetol. Rev. 25:26), this is the first report of snake predation on *C. melanosterna*.

We thank the Honduran Coral Reef Foundation and Operation Wallacea for supporting our research in the Cayos Cochinos.

EUMECES LATICEPS (Broad-headed Skink). **FRUGIVORY; SEED DISPERSAL.** Most lizard species are exclusively carnivorous, yet herbivorous or omnivorous species are known from 11 lizard families (Cooper and Vitt 2002. J. Zool. 257:487–517). Of these, at least 8 families contain frugivorous species. The family Scincidae is one such example with 18 species known to be herbivorous or omnivorous. Furthermore, Cooper and Vitt (*op. cit.*) assert that plant matter may comprise a small component of the diet of many skinks that are primarily carnivorous. *Eumeces laticeps* may be one such species. Although this species typically consumes arthropods, snails, *Anolis* lizards, and even congenerics (Vitt and Cooper 1986. J. Herpetol. 20: 408–415), it is also the only North American scincid documented to consume fruit. Cooper and Vitt (*op. cit.*) report that *E. laticeps* has been known to eat grapes and berries, but provide no specific information on plant taxa nor viability of ingested seeds. Here we report an instance of frugivory by *E. laticeps*, provide positive identification of the species of fruit consumed, and evidence that this species could function as a seed disperser.

At ca. 1300 h on 10 June 2005, GGS and SMB captured an adult male *E. laticeps* (119 mm SVL, 247 mm TL, 35 g) beneath an abandoned doghouse. This observation was made in a rural setting in North Auburn, Alabama (32°38'55"N, 85°27'17"W, datum: WGS84; elev. 198 m). Upon capture, the lizard passed a fecal pellet which we preserved in formalin. This pellet contained

53 seeds and a receptacle with its attached pedicel from the aggregate fruit of *Morus rubra* (Moraceae). The lizard was held in captivity for one week during which time it passed 11 more seeds, another receptacle and pedicel. Because two receptacles (each with attached pedicels) were found in association with a large number of seeds, at least two fruits were eaten. Additionally, the presence of the combination of receptacles, pedicels, and partially aggregated seeds makes it unlikely that the seeds were ingested secondarily. The tree of this species closest to the lizard's refugium was within 3 m. The identity of the seeds was verified using a seed identification guide (Martin and Barkley 1961. Seed Identification Manual. University of California Press, Berkeley, California. 221 pp.) and by comparison to freshly collected fruit. Seed viability was confirmed by placing 6 seeds on moistened filter paper in a Petri dish and another 5 seeds in ca. 5 mm of finely ground peat moss in a Petri dish on 26 June 2005. Dishes were misted with water and checked for germination daily. One seed germinated in the peat moss on 3 August 2005. On 29 August, seeds were removed from the Petri dishes for tetrazolium testing. Seeds were cut in half, soaked for 1 hour in a 1% tetrazolium chloride solution, and then examined under a dissecting microscope for tetrazolium staining (indicating cellular respiration and hence viability). Four of the 6 seeds placed on the filter paper tested positive. The other 2 seeds from this dish and all 5 from the peat dish were found to be empty when cut open; the endosperm appeared rotted away. This may be an artifact of the germination trial rather than the digestive action of the skink because the seed coat was intact. This was further verified by cutting open 10 of the 53 seeds first passed by the lizard which had been placed in formalin. All seeds in this sample also had intact endosperm.

Eumeces laticeps frequents openings and edges of hardwood forests (Palmer and Braswell 1995. Reptiles of North Carolina, UNC Press, Chapel Hill, North Carolina. 412 pp.) which increases the likelihood that seed will be deposited in a site suitable for germination. Field work documenting seed germination from *E. laticeps* scat deposited *in situ* will be necessary to confirm this hypothesis.

We thank William Clements for access to his property.

Submitted by **GEOFFREY G. SORRELL** (e-mail: sorregg@auburn.edu), **ROGER D. BIRKHEAD**, and **SCOTT M. BOBACK,** Department of Biological Sciences, Auburn University, Alabama 36849, USA .

GYMNOPHTHALMUS SPECIOSUS **(Spectacled Lizard),** ***BACHIA HETEROPA*** **(Earless Lizard). PREDATION.** Falconiform bird predation on lizards is well documented. Martín and López (1990. Smithson. Herpetol. Info. Serv. 82:1–43) compiled information about predation on lizards by 23 species of falconiformes in southwestern Europe. Castro and Restrepo (1987 Actualidades Biológicas 16:31) found four specimens of *Leptotyphlops goudotti* in the stomach of *Falco sparverius*. Reptiles are also important prey of the Common Buzzard, *Buteo buteo* (Selás 2001 Can. J. Zool. 79:2086–2093), and West (1975. Condor 77:354) reported a case of predation of *Amphisbaena fuliginosa* by *Buteo nitidus*. In Venezuela, accipiters and the Black-Faced Hawk (*Leucopternis melanops)* have been mentioned as predators on reptiles (Phelps and de Schauensee 1978. Una Guía de las Aves de Venezuela. Gráficas Armitano. Caracas. 484 pp.), but documented reports of hawk predation on reptiles are generally scarce. The most substantial data are those of Rivas et al. (1998. Herpetol. Rev. 29: 238–239), who reported 9 species of Accipitridae birds, including *Buteo magnirostris*, as predators on Green Iguanas (*Iguana iguana*). Hence, we augment limited reports of hawk predation on reptiles with several observations from Venezuela.

During a faunal inventory conducted on 11 April 1989, members of the staff of Dirección General de Fauna del Ministerio del Ambiente y de los Recursos Naturales, Venezuela, captured an adult (350 g, 395 mm) female Roadside Hawk (*Buteo magnirostris*) in the road between Coloradito and Chaguaramas, Municipio Independencia, Anzoátegui State (08°48'N, 63°27'W; elev. 90 m). The specimen (EBRG 10424) was deposited in the Museo de la Estación Biológica de Rancho Grande. During the preservation process, RR found four lizards in the crop that apparently had been swallowed recently, as they were only partially digested. Two specimens were identified as *Gymnophthalmus speciosus* (115.0 and 95.0 mm total length [TL]) and two as *Bachia heteropa* (140.0 and 183.0 mm TL), and catalogued as vouchers EBRG 2332–2333 and EBRG 2330–2331, respectively.

This is the first *B. magnirostris* predation record on *Gymnophthalmus* and *Bachia*. Occurrence of 4 specimens of 2 different species supports the idea that small reptiles may be more than occasional prey for this species, previously reported to feed almost exclusively on insects (Phelps and de Schauensee, *op. cit.*). Diurnal, open area (savanna and forest edges) foraging, and use of relatively low perches (5–15 m; Phelps and de Schauensee, *op. cit.*) might facilitate *B. magnirostris* predation on small diurnal lizards.

Sergio Bermúdez and Marco Natera verified, respectively, the *B. magnirostris* and lizard identifications. We thank A. Mijares-Urrutia, I. Martínez-Solano, F. Bisbal, and J. Sánchez for suggestions.

HEMIDACTYLUS FRENATUS **(Common House Gecko). REPRODUCTION.** That many gekkonid lizards have continuous reproduction with a fixed clutch size of two eggs is well known (Vitt 1986. Copeia 1986:773–786; Selcer 1990. Herpetologica 46:15–21), but nothing is known about reproduction of *Hemidactylus frenatus* from the Pacific Coast of Mexico (Ramírez-Bautista 1994. Manual y Claves Ilustradas de los Anfibios y Reptiles de la Región de Chamela, Jalisco, México. Universidad Nacional Autónoma de México, Ciudad de México, D.F., México. 127 pp.). Hence, this note provides preliminary data on *H. frenatus* reproduction in Pacific México.

During 1989, we studied reproductive activity in *H. frenatus* through the year in the Biological Reserve Estación de Biología Chamela. This area is located between 5 km N and 15 km S of the

Pacific Coast of Jalisco, México (19°30'N, 105°03'W, datum: WGS84; elev. 10 m). Habitat is tropical dry forest dominated by *Astronium graveolens*, *Thouinidium decandrum*, and *Couepia polyandra* (Bullock 1986. Archiv. Meteorol. Geophys. Bioclimat. 36:297–316); precipitation occurs June–October. Mean annual temperature is 24.9°C; mean annual rainfall is 748 ± 119 mm (Ramírez-Bautista and Vitt 1997. Herpetologica 53:423–431). *Hemidactylus frenatus* inhabits crevices of the buildings at this field station.

Eight females (mean SVL 52.6 ± 1.2 mm, range: 50.0–58.0 mm, N = 8) from January (N = 2), April (N = 3), and August (N = 3) were reproductively active. Females from January and April had vitellogenic follicles (VF) and eggs, and females from August had eggs and growing follicles. Females with VF (N = 3) averaged 55.7 ± 2.3 mm SVL and females with eggs (N = 5) averaged 50.8 ± 0.6 mm SVL. Volume of VFs averaged 68.8 ± 24.5 mm^3 (range: 28.3–112.8 ± mm^3, N = 3) whereas egg volume averaged 258.0 mm ± 26.6 mm^3 (range: 197.5–322.9 mm^3, N = 5). Females laid 2 clutches of two eggs.

The reproductively active condition of females in all months sampled implies that reproduction occurs year-round and that *H. frenatus* may produce 3–4 clutches a year similar to many other tropical gekkonid lizard species (Vitt 1986, *op. cit.*).

HOPLODACTYLUS MACULATUS **(Common Gecko). TOXIN CONSUMPTION.** Anticoagulant poisons, particularly the second-generation anticoagulant brodifacoum, are used extensively both to eradicate pest mammals from offshore islands and to detect reinvasions (e.g., Dilks and Towns 2000. Developing Tools to Detect and Respond to Rodent Invasions of Sslands: Workshop Report and Recommendations, Science Internal Series 59, Department of Conservation, Wellington, New Zealand, 18 pp.). Conservation benefits of pest mammal eradication usually outweigh the costs of temporary population die-back of non-target natives (Innes and Barker 1999. New Zealand J. Ecol. 23:111–127). Considerable research documents brodifacoum poisoning of native bird species (reviewed by Eason et al. 2002. Ecotoxicology 11:35–48) and invertebrates (e.g., Spurr and Drew 1999. New Zealand J. Ecol. 23:167–173) following mammalian pest eradication. However, research on other taxa (e.g., reptiles) and on ecosystem-level effects of chronic brodifacoum use is sparse. Brodifacoum is a potent and persistent rodenticide, lasting for at least six months in organs and tissue, which exacerbates the risk of secondary poisoning of non-target species (e.g., Eason et al., *op. cit.*).

Potential risk of brodifacoum poisoning to reptiles is thought to be low, as reptiles have a blood coagulation chemistry distinct from that of mammals (Merton 1987. Dodo J. Jersey Wildl. Preserv. Trust 24:19–43). However, few studies have investigated anticoagulant bait consumption by reptiles in the wild (but see Merton, *op. cit.* and Thorsen et al. 2000. Biol. Conserv. 96:133–138).

Mana Island, Cook Strait, New Zealand (41°40'S, 174°00'E) underwent eradication of mammals in 1991 and has since been the focus of an intensive ecological restoration program. To protect Mana Island from mammal reinvasion, 42 wooden boxes baited with brodifacoum poison (Pestoff®; 20 ppm; which has a half-life of 157 days in soil) and peanut-oil flavored wax tags are deployed along the shoreline, and rebaited regularly (every 4–6 weeks). Common geckos (*Hoplodactylus maculatus*) regularly use the bait boxes as refugia (Hare and Hoare 2005. Herpetol. Rev. 36:179).

In May 2004, we surveyed *H. maculatus* from 14 bait boxes. Handling induced defecation by 16% (12 of 74) of geckos. We observed 3 adult (one male and two females; 69–81 mm SVL) geckos (25%) deposit bright blue-green fecal material, in contrast to normal, dark-brown feces. One other adult (73 mm SVL) male gecko exhibited blue/green spots inside the throat and abdominal skin. Blue-green fecal material deposited was the same color as the dyed brodifacoum bait within the boxes, which led us to infer consumption of the toxin by these geckos (based on Freeman et al. 1996. Wildlife Research 23:511–516). One of the three geckos that defecated bait was in the late stages of pregnancy with two embryos (as determined by palpation), which raises the question of whether anticoagulant poison might detrimentally affect offspring. Other than these obvious signs that geckos consume toxic bait, all appeared to be in good condition (body condition, defined as log(mass)/log(SVL), was 0.557 ± 0.086, and did not differ significantly from body condition of adult geckos that did not show signs of bait consumption 0.536 ± 0.079; $F_1 = 0.4946$, $P = 0.4839$), had few ectoparasites and no sores or open wounds. Only one gecko was found dead during the survey, a desiccated juvenile, with no evidence of brodifacoum consumption.

Our observation of bait consumption by *H. maculatus* in nature is the first to document both brodifacoum consumption by geckos and consumption of a toxin by reptiles when it is continuously provided. Only two published studies report reptile consumption of brodifacoum bait in the wild. Following pest mammal eradication on Round Island, Mauritius, Telfair's Skink (*Leiolopisma telfairi*) suffered mortality from consuming brodifacoum bait (Merton, *op. cit.*), and Wright's Skink (*Mabuya wrightii*) from Frégate Island, Seychelles, also consumed brodifacoum bait, though effects on these skinks were not studied (Thorsen et al., *op. cit.*).

Formulating management strategies to mitigate the potential effects of anticoagulants and other toxins on lizards is hampered by a lack of information (Spurr 1993. Conservation Advisory Notes 33, Department of Conservation, Wellington, New Zealand, 4 pp.). Published lethal dose (LD_{50}) data on acute toxicity of anticoagulants to reptiles do not exist. However, LD_{50} data for lizards exposed to sodium monofluoroacetate (1080) suggest that poisons are unlikely to induce mortality in lizards, as lethality would require vast quantities of toxin to be consumed (e.g., McIlroy et al. 1985. Austral. Wildl. Res. 12:113–118). The hypothesis that anticoagulant poisons are unlikely to pose lethal threats to reptiles is supported by a laboratory study of anticoagulant consumption by McCann's Skinks (*Oligosoma maccanni*). Skinks which consumed toxic pindone (a first-generation anticoagulant) bait (97%), showed no adverse short-term effects (Freeman et al., *op. cit.*). However, potential sub-lethal effects of anticoagulants include interference with reptiles' abilities to thermoregulate, which might prove fatal under conditions of environmental stress (Merton, *op. cit.*).

Traditionally, discussions concerning the risk of secondary poisoning to non-target native species have focussed on target (i.e., mammalian) prey species as vectors for anticoagulant transportation (e.g., Eason and Wickstrom 2001. Vertebrate Pesticide Toxicology Manual (Poisons) (2nd ed.), Technical Series 23, Department of Conservation, Wellington, New Zealand, 122 pp.). Our finding extends concerns for non-target species, as brodifacoum consumption by reptiles poses a risk of secondary poisoning, particularly to native avian predators of lizards. Brodifacoum is a highly potent and persistent anticoagulant; ecosystem-level research is required if continued use of brodifacoum is deemed an appropriate management option to detect rodent invasions.

We thank C. L. Stephens and G. D. Timlin for field assistance, C. H. Daugherty and J. A. Moore for comments on the draft and D. V. Merton for helpful discussions. Our research was conducted with Department of Conservation approval (permit 9/375 ROA).

LEIOCEPHALUS CARINATUS ARMOURI (Northern Curlytail Lizard). **SCAVENGED ROAD-KILL.** Little is known about the vertebrate predators and scavengers of *Leiocephalus carinatus armouri* within its introduced range in Florida, with few of these consumers currently documented (e.g., Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida, Krieger Publishing Company, Malabar, Florida. 155 pp.; Smith and Engeman 2004a. Herpetol. Rev. 35:169–170; Smith and Engeman 2004b. Florida Field Nat. 32:107–113; Dean et al. 2005. Herpetol. Rev. 36:451). Thus far, only one mammal in Florida has been verified, feral cats (*Felis catus*) (Smith and Engeman 2004b, *op. cit.*). Here we report Eastern Gray Squirrel (*Sciurus carolinensis*) scavenging of a road-killed *L. c. armouri* in Florida.

At 1155 h on 1 April 2005 (sunny, air temperature ca. 28.3°C), HTS observed an adult *S. carolinensis* at the Woolbright Road colony of *L. c. armouri* located in Boynton Beach, Florida (see previous colony site descriptions in Smith and Engeman 2003. Herpetol. Rev. 34:245–246), sitting on its haunches in the parking lot of the Woolbright Road site gnawing on a large, flattened, wafer-like object . Holding the "wafer" in its forelimbs, the squirrel spun it slowly while chewing off and swallowing the edge portions. This behavior was observed for 3–4 min, at which time the squirrel was more closely approached. The squirrel then nervously flicked its tail, gave two distress barking-chatters, and attempted to flee with the wafer in its jaws. The large and unwieldy size and shape of the wafer caused it to be dropped by the squirrel after it had moved only 5 m. The wafer was collected and identified as a road-killed, completely flattened, adult *L. c. armouri* (see Fig. 1).

Leiocephalus c. armouri, present at the Woolbright Road site since at least 1986 (Smith and Engeman 2003, *op. cit.*), has been intensively studied there since 1993 (Smith and Engeman 2004b, *op. cit.*) and road-kills are common. During regular morning walks around the site, *L. c. armouri* road-kills are often found, only to disappear within a day or two. Feral cats (*Felis catus*) and exotic rodents were previously thought largely responsible for these disappearances. However, *S. carolinensis* have always been the most common mammal at the colony site.

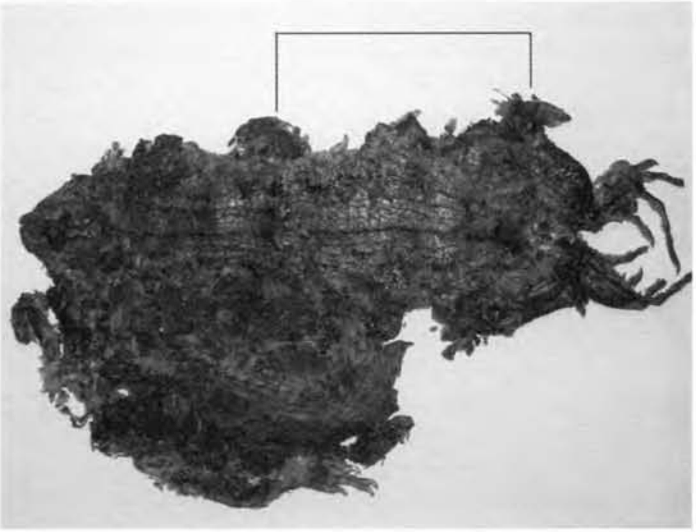

Fig. 1. Roadkilled *Leiocephalus carinatus armouri*; the bracket indicates the area chewed on by a *Sciurus carolinensis*.

In Florida, the diet of *S. carolinensis* generally consists of plant material including fruits, acorns, other mast and drupes, vegetative buds, bulbs, fungi, and staminate cones (Brown 1997. Mammals of Florida, Windward Publishing, Inc., Miami, Florida. 224 pp.; HTS, pers. obs.). However, *S. carolinensis* are also known to be carnivorous at some localities and times of the year, consuming insects, bird eggs, birds, and even chipmunks (Layne and Woolfenden 1958. J. Mammal. 39:595–596; Korschgen 1981. J. Wildl. Manage. 45:260–266; Faccio 1996. Can. Field Nat. 110:538). The relative abundance of *L. c. armouri*, alive and as road-kill, at the Woolbright Road colony may make it an important protein and trace element (e.g., calcium) dietary component of *S. carolinensis* at this location, especially during the bimodal squirrel breeding season peaks in Florida of late winter/early spring, and late spring/summer (Brown, *op. cit.*). Future observations/examinations/collections of *L. c. armouri* carcasses at this site will attempt to further clarify such a relationship.

LIOLAEMUS OLONGASTA (NCN). **BODY TEMPERATURE.** *Liolaemus olongasta* is an oviparous lizard inhabiting the hot arid landscape of the Monte Phytogeographic Province in northern Argentina (Cabrera and Willink 1980. Biogeografía de América Latina. Washington, D.C. 109 pp.). Known from extreme western La Rioja Province and San Juan Province at elevations between 900 and 1600 m (Etheridge 1993. Museo Regionale di Scienze Naturali 11:1–199), data on its biology are sparse. Limited study

has been devoted to thermoregulation, sexual dimorphism, and time budgets (Cánovas et al. 2001. Congr. Argentina Herpetol. IV:32–33; Cánovas et al. 2002. XVI Reunión de Com. Herpetol. Asoc. Herpetol. Argentina XVI:45; Cánovas et al. 2003. Reunión de Com. Herpetol. Asoc. Herpetol. Argentina. XVII:38). Here, we add data addressing the thermal ecology of this species.

Field work was carried out in a dry streambed with a mosaic of flat boulders and patches of sand in La Laja, Departamento Albardon, Provincia de San Juan, Argentina (31°19'S; 68°41'W, datum: WGS84; elev. 700 m. Data were collected every 10 days from August 2000 to August 2001 by revisiting bushes and boulders across the study site at random. Each individual was hand-captured. Cloacal temperature (T_c), substrate temperature (T_s) and air temperature (T_a) were measured with a rapid reading Miller-Weber thermometer to the nearest 0.1°C. For each capture, we took T_s on the substrate at the exact point of observation, and T_a 1 cm above the substrate.

Mean body temperature was 32.1°C (s = 3.9°C, N = 55). We found no differences in T_c between males and females (ANOVA: $F_{1,53} = 2.77$, $P > 0.05$). Using size (as SVL) as the covariate, we also found no differences in T_c between gender groups (ANCOVA: $F_{2,51} = 2.02$, $P > 0.05$); a pattern similar to *Liolaemus pseudoanomalus* (Villavicencio et al. 2001. Congr. Argentina Herpetol. IV:81–82). However, using T_a as the covariate, we found interseasonal differences in T_c (ANCOVA: $F_{3,50} = 9$, $P < 0.05$); an *a posteriori* Tukey test revealed that T_c during winter (July to September) differed from other seasons. Cloacal temperature was correlated with each of T_s and T_a ($r = 0.64$, $P < 0.0001$; $r = 0.80$, $P < 0.0001$, respectively).

Liolamus olongasta appears more heliothermic that thigmothermic. This species thermoregulates in a manner similar to *L. wiegmanni* (Martori et al. 1998. Rev. Esp. Herpetol. 12:19–26), *L. sanjuanensis* (Acosta et al. 2004. Herpetol. Rev. 35:171), and *Liolaemus koslowsky* (Martori et al. 2002. Cuad. Herpetol. 1:78–99). These species move among shading vegetation during the warmer hours to lower their body temperature.

LIOLAEMUS QUILMES (NCN). **LONGEVITY.** Little is known about longevity in Neotropical *Liolaemus*. Age at first reproduction or reproductive frequency can help estimate relative longevity. Tinkle (1969. Amer. Nat. 103:501–516) suggested that early maturing, multiple-brooded species tend to have shorter life expectancies than late-maturing, single-brooded species. Subsequent research (Stearns 1992. The Evolution of Life Histories, Oxford University Press, Oxford. 249 pp.; Roff 2001. Life History Evolution. Sinauer Associates, Sunderland, Massachusetts. 527 pp.) has generally borne this out. In *Liolaemus*, little information exists on age at first reproduction (e.g., ~12 months in *L. lutzae*, Rocha 1992. J. Herpetol. 26:17–23; 18 months in *L. signifer*, Pearson 1954. Copeia 1954:111–116). More data exist for reproductive effort. Two or 3 clutches may be produced each season (*L. koslowskyi*, 2 clutches, Aun and Martori 1998. Cuad. Herpetol. 12:1–9; *L. lutzae*, 2 or 3 clutches, Rocha 1990. Ciencia e Cultura 42:1203–1206; *L. multimaculatus*, 2 clutches, Vega 1997. Herpetol. J. 7:49–53; *L. scapularis*, 2 clutches, Ramirez Pinilla 1994. J. Herpetol. 28:521–524; *L. wiegmannii*, 2 clutches, Martori and Aun 1997. J. Herpetol. 31:578–581) or only one brood either every 1 or 2 years (*L. elongatus*, Ibargüengoytía and Cussac 1998. Herpetol. J. 8:99–105), or 2 or 3 years (*L. pictus*, Ibargüengoytía and Cussac 1996. Herpetol. J. 6:137–143). *Liolaemus quilmes* from northwestern Argentina produces one clutch per season (Ramirez Pinilla 1992. Acta Zool. Lilloana 42:41–49). This suggests that *L. quilmes* may have an intermediate life expectancy relative to other *Liolaemus*. Here I provide preliminary data on this life-history trait for *L. quilmes* that can ultimately be used to test the intermediate longevity hypothesis.

As part of a separate study (Halloy and Robles 2002. Bull. Maryland Herpetol. Soc. 38:118–129; Halloy and Robles 2003. Cuad. Herpetol. 17:65–71), *Liolaemus quilmes* was monitored over 6 austral spring and summers (October 1999–March 2005) at Los Cardones (26°40'1.5"S, 65°49'5.1"W, datum: WGS84; elev. 2700 m), Tucumán, Argentina. This diurnal, mainly insectivorous, and oviparous lizard occurs in semi-arid and arid habitats between 1600–3000 m (Etheridge 1993. Boll. Mus. Reg. Sci. Nat., Torino 11:137–199). Males are more colorful and slightly larger (mean SVL = 65 mm) than the less conspicuous, slightly smaller (mean SVL = 61 mm) females (Cei 1993. Mus. Reg. Sci. Nat., Torino Monogr. 14:1–949).

Lizards were captured within a 60 x 60-m grid (Halloy and Robles 2002, *op. cit.*). They were measured, weighed and individually marked with a combination of two colored beads attached to the base of the tail with surgical steel monofilament (Fischer and Muth 1989. Herpetol. Rev. 20:45–46). Marked lizards were released at the site of capture. Because of the risk to smaller lizards, only adults were marked. Young grow rapidly during their first two summers and can breed by the beginning of their third summer, at 20–21 months. Thus, I estimated adults captured to be ≥ 1.5–2 years old.

Over the study, 189 lizards (95 males and 94 females) were marked. Lizards sighted ≤ 3 times each summer (N = 51), and those marked during the last summer (N = 35) were excluded from the analysis. Remaining lizards (N = 103: 48 males, 55 females)

TABLE 1. Number of adult female (male) *Liolaemus quilmes* resighted over 5 years with respect to year (i.e., austral spring/summer = October–March) of capture.

Year of capture	Number of years resighted					
	1	2	3	4	5	Totals
1999–2000	2(1)	4(9)	1(4)	4(0)	1(1)	12(15)
2000–2001	0(1)	3(4)	3(4)	0(1)	2(1)	8(11)
2001–2002	0(0)	0(0)	0(1)	1(0)	0(0)	1(1)
2002–2003	2(5)	10(2)	7(5)	0(0)	0(0)	19(12)
2003–2004	0(2)	15(7)	0(0)	0(0)	0(0)	15(9)
Totals	4(9)	32(22)	11(14)	5(1)	3(2)	55(48)

represent animals periodically censused during the October–March interval over 84 days in the 6 years combined (Table 1).

Most lizards appeared to live at least 2 or 3 summers as breeding adults (75% males, 78.2% females; Table 1). No lizard marked during the first summer was found during the sixth summer. Of those marked during the first summer, 6.7% males and 8.3% females were found 5 years later. Of those marked during the second summer, 9.1% males and 25% females were found 5 years later. Only two lizards were marked during the third summer and they were resighted for 3 (a male) and 4 years (a female). Adding ca. 2 years since hatching before their first capture, this suggests that these lizards may live, on average, 4–5 years. Seven to 25% of individuals may attain 7 years of age. No significant difference was found between males and females in the pattern of years resighted (Wilcoxon-Mann-Whitney test: $W_x = 29$, $P > 0.05$; Siegel and Castellan 1988. Statistics for the Social and Behavioral Sciences. McGraw-Hill, Inc., New York, 399 pp.).

This temperate species seems to fall in a middle of a continuum between early-maturing species having multiple broods and short life expectancies and late-maturing species producing one brood and having high survivorship (Tinkle, *op. cit.*). However, longevity data obtained for other species of *Liolaemus* will be needed to unequivocally verify this supposition.

I thank C. Robles, M. Castillo, and C. Guerra for field assistance; R. Espinoza and M. Hayes for their comments and for improving the text; Recursos Naturales y Suelos, Tucumán Province for permission to access the site (Permits 394-98, 95-2000, and 539-RN); and PIP-CONICET 4966/97 and 02668, and CIUNT 26/G218 for financial support.

LIOLAEMUS RUIBALI **(NCN). BODY TEMPERATURE.** *Liolaemus ruibali* is an ovoviviparous insectivorous lizard that inhabits the east slope of the Andean Cordillera and pre-Cordillera in central-western Argentina (Cei 1986. Museo Regionale di Scienze Naturali. Monografie IV. Torino. 527 pp.). *Liolaemus ruibali* has an ambiguous conservation status: defined as a species for which "insufficient knowledge" exists (Lavilla et al. 2000. Categorización de los Anfibios y Reptiles de la República Argentina. Asoc. Herpetol. Arg., 97 pp.). Data on its biology are sparse. The only published data are those of Villavicencio et al. (2004. Actas V Congr. Arg. Herpetol. pp. 64–65, San Juan), who made observations on its reproduction and diet. Here, we present preliminary data on *L. ruibali* thermal ecology.

On 14 April 2000, we conducted field work in the Reserva de Usos Múltiples Don Carmelo, Departamento Ullum, Provincia de San Juan (31°10'S, 69°46'W, datum: WGS84; elev. 3000 m). Located in the Puna Phytogeographic Province, *Stipa speciosa var. breviglumis, Lycium chanar, Artemisia mendocina, Ephedra breana,* and *Maihuniopsis glomerata* dominate the largely Andean flora (Cabrera and Willink 1980. Biogeografía de América Latina. Washington, D.C. 109 pp.). The data presented are based on 12 captures. To collect these data, we revisited a randomized selection of bushes and low rocks across the study site. Each individual was captured by hand, and its SVL was measured (to nearest 0.02 mm). For each capture, cloacal (T_c), substrate (T_s) and air (T_a) temperatures were measured (to nearest 0.1°C) with a rapid-reading Miller-Weber thermometer. We took T_s at the exact point of observation, and T_a 1 cm above the substrate, both immediately following capture.

Mean body temperature of the 12 *L. ruibali* was 24.4°C (SD = 6.2°C). Body size was unrelated to T_c (Spearman Rank Correlation: $r_s = 0.22$, $P = 0.47$). An ANOVA revealed significant differences between T_c (higher) and T_a ($F_{1,22} = 6.64$, $P = 0.01$). In contrast, neither T_c and T_s ($F_{1,22} = 1.54$, $P = 0.22$) nor T_a and T_s ($F_{1,22} = 2.26$, P = 0.14) differed significantly from one another. Cloacal temperature and each of T_s and T_a were correlated (Spearman Rank Correlation: $r_s = 0.90$, $P = 0.00005$; $r_s = 0.85$, $P = 0.0004$, respectively). All captured animals were basking near *Ctenomys* (rodent) burrows. Of the 12 animals, 5 attempted to escape into *Ctenomys* burrows.

Based on correlation coefficient similarity among T_c, T_s and T_a, thermoregulation likely occurs predominantly through conduction, similar to *L. pseudoanomalus* (Villavicencio 2004. Ecología Térmica y Actividad Espacio - Temporal de una Población de *Liolaemus pseudoanomalus* [Cei 1981] [Iguania: Liolaemidae] del Departamento de Albardón, San Juan, Argentina. Licenciatura dissertation. Unv. Nat. San Juan. 42 pp.). This differs from *L. wiegmanni* (Martori et al.1998. Rev. Esp. Herpetol. 12:19–26), *L. olongasta* (Cánovas et al. 2001. Congreso Arg. Herpetol. V:32–33), *L. koslowsky* (Martori et al. 2002. Cuad. Herpetol. 1:78–99), and *L. sanjuanensis* (Acosta et al. 2004. Herpetol. Rev. 35:171), which show a stronger relationship between T_c and T_a, implying that convection is more important.

Submitted by **HÉCTOR JOSÉ VILLAVICENCIO***, **CÁNOVAS MARIA GABRIELA**, and **JUAN CARLOS ACOSTA,** Departamento de Biología, Facultad de Ciencias Exactas, Físicas y Naturales, Universidad Nacional de San Juan. *Becario CONICET, Avenida España 400 (N), Caixa Postal 5400, San Juan, Argentina.

MABUYA BISTRIATA **(Trinidad Skink). REPRODUCTION.** *Mabuya bistriata* is generally described as being both terrestrial and arboreal, with females being slightly larger than males (Vitt and Blackburn 1991. Copeia 1991:916–927). Breeding has been noted as occurring as July–August for mainland and island populations (Murphy 1997. Amphibians and Reptiles of Trinidad and Tobago. Krieger Publishing Co., Malabar, Florida. 245 pp.). In this report, we augment information on its reproductive behavior with an instance of arboreal courtship in May at the end of the dry season in Trinidad.

On 28 May 2003 at 1000 h EST, we observed a pair of *M. bistriata* engaged in courtship on the side of a fiberglass wall of the shower 1.8 m above the ground at our base camp at Petit Tacaribe on the northern coast of Trinidad (10°47'48"N, 61°12'33"W; datum: WGS84; elev. 10 m). Local vegetation consists of a diverse assemblage of evergreen trees including several species of palms, bromeliads, and an understory dominated in many places by *Heliconia*. The male was partially astride the visibly larger female and grasping the ventrolateral skin just behind her left shoulder with his jaws (the female made no effort to resist the male). The animals were observed for 10 min and then an attempt

was made to capture them. The male (95.9 mm SVL) was collected; the female eluded capture.

Our observation indicates that mating in *M. bistriata* can occur outside of the rainy season (June–December) in Trinidad and might occur earlier in the year than previously reported. The male was deposited in the herpetological collection of the United States National Museum (USNM 561864) in Washington, D.C.

Submitted by **MICHAEL K. MOORE**, Department of Biology, Mercer University, Macon, Georgia 31207, USA (e-mail: moore_mk@mercer.edu); and **VICTOR R. TOWNSEND, JR.**, Department of Biology, Virginia Wesleyan College, 1584 Wesleyan Drive, Norfolk/Virginia Beach, Virginia 23502, USA.

MICROLOPHUS PERUVIANUS (Peruvian Pacific Iguana) **SAUROPHAGY**. *Microlophus peruvianus* occupies a broad geographic range in western South America from northern Ecuador to southern Peru (Dixon and Wright 1975. Los Angeles Co. Mus. Contri. Sci. 271:1–39). Inhabiting open, arid landscapes, *M. peruvianus* seems to prefer intertidal habitats such as sandy and pebbled beaches, cliffs and other near-shore structures. Herein, I report two observations of saurophagy in *M. peruvianus* from southern Peru, both involving *Phyllodactylus* geckos as prey.

At 1330 h on 19 July 2003, I captured a male *M. peruvianus* (90.8 mm SVL) on La Vieja Island, Paracas National Reserve, Department Ica (14°17'32.8"S, 76°10'31"W [datum: WGS84]; elev. < 5 m). The lizard was found near a South American sea lion (*Otaria flavescens*) carcass about 20 m away from the intertidal zone on a boulder and cobble beach. I flushed the stomach of the lizard with water and recovered the 25-mm piece of the tail of a *Phyllodactylus angustidigitus*. I also recovered parts of intertidal crab and isopods, a spider, and a fly. *Phyllodactylus angustidigitus* is the only gecko species known to occur on La Vieja. This species is often observed under sea lion carasses, a microhabitat frequently shared with *M. peruvianus*. For example, on 19 July 2003, I found two juvenile *P. angustidigitus* under the sea lion carcass close to where I captured the aforementioned *M. peruvianus*. This proximity may favor predation. After stomach flushing, the *M. peruvianus* was released at the point of capture.

On 18 December 2003, I watched a male subadult *M. peruvianus* (69.3 mm SVL) prey on a male of *Phyllodactylus microphyllus* (28.6 mm SVL). The interaction occurred along a streamlet facing a rocky beach near the western tip of the Illescas Peninsula, Departamento Piura (5°47'08.0"S, 81°04'17.4"W; GPS coordinates; elev. < 5 m). After noticing the moving gecko, the *M. peruvianus* made several attempts to catch it, repeatedly failing. After less than 2 minutes, the lizard finally caught and ingested the gecko headfirst. The gecko did not lose its tail during ingestion. I captured the *M. peruvianus* and flushed its stomach to collect data on the size of both lizards. The *M. peruvianus* was then released at the point of capture.

Saurophagy has been reported in members of the *Microlophus occipitalis* group from the Galapagos Islands (Schluter 1984. Oikos 43: 291–300; Stebbins et al. 1967. Ecology 48:839–851) and recently in members of the *peruvianus* group from Peru (Perez 2005. Herpetol. Rev. 36:63; Perez and Balta 2005. Herpetol. Rev. 36:63).

Florida International University Institutional Animal Care and Use committee (Protocol Approval Number 01-009) approved stomach flushing of the *M. peruvianus*.

Submitted by **ALESSANDRO CATENAZZI**, Department of Biological Sciences, OE167, Florida International University, Miami, Florida 33199, USA; e-mail: acaten01@fiu.edu.

OEDURA MARMORATA (Marbled Velvet Gecko). **ENDOPARASITES.** *Oedura marmorata* is known from eastern, central, and northern Queensland, excluding northeastern Queensland; adults average 90 mm SVL (Cogger 1996. Reptiles & Amphibians of Australia, 6th Ed., Ralph Curtis Publ., Sanibel Island, Florida, 808 pp.). To our knowledge, no parasites have been reported from *O. marmorata*. The purpose of this note is to report the nematodes *Pharyngodon kartana* (in large intestine) and *Abbreviata* sp. (in body cavity), and the pentastome *Raillietella scincoides* (in lungs) in *O. marmorata*.

Three adult *O. marmorata* (mean SVL: 89 mm ± 12 SD, range: 75–97 mm) from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California were examined for endoparasites. Lizards (LACM 57001–57003) were collected October 1966 near Mt. Doreen (22°07'S, 131°21'E, datum: AGD66; elev. 750 m) Northern Territory, Australia. Lungs, small and large intestines were opened and their contents were examined using a dissecting microscope. Stomachs were unavailable for examination. Endoparasites were cleared in concentrated glycerol, identified and deposited in the United States National Parasite Collection (USNPC) as *Pharyngodon kartana* (96977), *Abbreviata* sp. (larvae) (96976) and *Raillietella scincoides* (96978).

Found were 24 *Pharyngodon kartana* (prevalence, infected lizards/lizards examined x 100 = 67%); mean intensity, mean number nematodes per infected lizard = 12.0 ± 7.1 SD; range:7–17; 4 *Abbreviata* sp. (prevalence, 75%, mean intensity 1.3 ± 0.58 SD, range 1–2; *Raillietiella scincoides* (prevalence 75%, mean intensity 4.0 ± 3.0 SD. range 1–7).

Goldberg and Bursey (2000. Trans. Royal Soc. South Aust. 124:127–133; and 2001. J. Roy. Soc. West. Aust. 84:23–27) reported other hosts for *Pharyngodon kartana*. This nematode species is restricted to Australian lizards. *Pharyngodon kartana* is an oxyurid nematode that has a direct life cycle that does not involve an intermediate host (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission, 2nd Ed. CABI Publ. Oxon, UK, 650 pp.). Larvae of *Abbreviata* sp. are commonly found in the body cavities and viscerae of Australian lizards and snakes (Goldberg and Bursey 1995. J. Helminthol. Soc. Washington 62:237–238; Jones 1995. J. Wild. Dis. 31:299–306; Goldberg et al. 1999. J. Helminthol. Soc. Washington 66:89–92). Small lizards are thought to serve as intermediate hosts for some species of *Abbreviata* because mature individuals have not been found in these lizards; mature individuals are frequently found in large lizards and other carnivores which feed on small lizards (Goldberg and Bursey 1995, *op. cit.*). Ali et al. (1984. Syst. Parasitol. 6:147–160) described *Raillietiella scincoides* from *Tiliqua scincoides* and it was later reported from *Nephrurus laevissimus* (Bursey and Goldberg 1999. J. Helminthol. Soc. Washington 66:175–179). *Oedura marmorata* is the third reported host. Most pentastomids mature in reptiles; intermediate hosts include insects and other reptiles (Roberts and Janovy 2005. Gerald D. Schmidt & Larry S.

Roberts' Foundations of Parasitology. 7th Ed. McGraw Hill Higher Education, Boston, 702 pp.). *Oedura marmorata* represents a new host record for *Pharyngodon kartana*, *Abbreviata* sp., and *Raillietella scincoides*.

We thank Christine Thacker (LACM) for permission to examine *O. marmorata* and Amanda Woolsey for assistance with dissections.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

PHRYNOSOMA CORNUTUM (Texas Horned Lizard). **MORTALITY**. Human activities can dramatically increase mortality rates in many wildlife populations, but most documentation exists for mammals and birds. Among reptiles, varied impacts linked to human activities are thought to exist, but documentation is rare. For example, in *Phrynosoma cornutum*, skewed sex-ratios in road-collected animals in spring can result in male-biased road mortality (Sherbrooke 2002. Herpetol. Rev. 33:21–24) and might be responsible for regional declines (Sherbrooke 2003. Introduction to Horned Lizards of North America. Univ. California Press, Berkeley. 177 pp.). Hence, we report a human activity-linked observation of unusual mortality event in *P. cornutum* from northern Mexico .

During a study of *Gopherus berlandieri* demography in August 1997, we surveyed the herpetofauna of Nueva Casilla, municipalidad of Escobodo, Nuevo Leon (25°48'51"N, 100°16'35"W, datum: NAD27; elev. 618 m). Among habitats examined was a clandestine waste-disposal site with building materials, aluminum cans, plastics, and three old automobile tires. In one tire, we found the dried remains of four desiccated adult (range 90–111 mm SVL) *P. cornutum*.

The lizards probably entered the tire seeking refuge and were unable to escape once inside; the inwardly curving tire walls likely prevented escape. August daytime temperatures in the shade can reach 45°C (INEGI, Carta de Clima, 1986 Mexico), and daytime temperatures in such a well-insolated artificial habitat would likely exceeded that value, rapidly killing the lizards. This observation illustrates that better regulation of waste material disposal in Mexico, especially discarded tires, could easily avert this source of mortality.

We thank Wade C. Sherbrooke for his help with *Phrynosoma* work and for reviewing this note.

PHRYNOSOMA DOUGLASII (Pigmy Short-horned Lizard). **COPULATORY POSITION.** Sherbrooke and Beltran-Sanchez (2005. Herpetol. Rev. 36:64–65) recently reviewed copulatory positions in the genus *Phrynosoma*. They described *P. asio* as using a distinctive position in which the male first grasps the female in the nuchal region (including cephalic spines) and then flips the female onto her back and grasps her with all four legs. This belly-to-belly position was described first for *P. coronatum* (Wood 1936. Copeia 1936:177) but is unknown in other *Phrynosoma* (Sherbrooke and Beltran-Sanchez, *op. cit.*). Here, I report a third species of *Phrynosoma* using a variant of this position.

During 1976 and 1977, I conducted a mark-recapture study of *Phrynosoma douglasii* and *Sceloporus graciosus* on a 1-ha study site in southeastern Idaho (Guyer and Linder 1985. Northwest Sci. 59:294–303; Guyer and Linder 1985. Great Basin Nat. 45:607–614; Guyer 1991. Amphibia-Reptilia 12:373–384). At 1110 h on 10 May 1977, I recaptured an adult (65 mm SVL) female *P. douglasii* on the dirt road leading to the site; she was released after a brief (< 1 min) processing interval. Upon leaving the study site at 1645 h, I re-encountered this female apparently copulating with an adult (53 mm SVL) male. The lizards were positioned belly-to-belly and on their sides, with the male biting the skin of the gular fold of the female while both sexes grasped each other with their limbs (Fig. 1a). A hemipenis of the male was everted but I could not confirm which side it was from or that it was inserted into the female's cloaca. Over a 5-min observation period the male instigated short (< 10 sec) bouts of activity during which both lizards moved their limbs, rotated their bodies on the ground, and alternately entwined and disentwined their tails. While taking photographs of the pair, I inadvertently startled the male, who disengaged from the female and fled about 5 m while the female righted herself and remained motionless.

As the male was unmarked, I captured and marked him and then (1650 h) returned him to the proximity of the female, who had not moved. The female immediately assumed a posture in which her body was held off the ground, but with her forequarters closer to the ground than her hindquarters. Her tail was curled over her back, exposing the cloacal area. The male did not move for ca. 5 sec and then rushed the female and bit her left forelimb. They thrashed violently for a few seconds until both were on their backs; the male then righted himself while still biting the female's forelimb. The female initiated a bout of activity that nearly succeeded in achieving the position observed at 1645 h, but they ended up with the female on her back and the male nearly righted but at a 45° angle to the female's left side (Fig. 1b). Over the next 40 min, the pair displayed 16 short bouts of activity (< 10 sec each) initiated by the male followed by 1–5 min periods of quiescence. The female waved her limbs during these bouts but never attempted to right herself and the male arched his back, forcing his cloaca into the ground. At 1729 h, my movements again frightened the male and he ran 1 m to the side of the road. The female remained on her back for ca. 2 min until I righted her.

These observations reveal the occurrence of a copulatory position in *Phrynosoma douglasii* similar to that observed in *P. asio* and *P. coronatum*. Sherbrooke and Beltran-Sanchez (*op. cit.*) speculated that this position and the behaviors leading to it indicate that female choice is limited and that the position can allow males to mate while avoiding potential damage from the female's cephalic

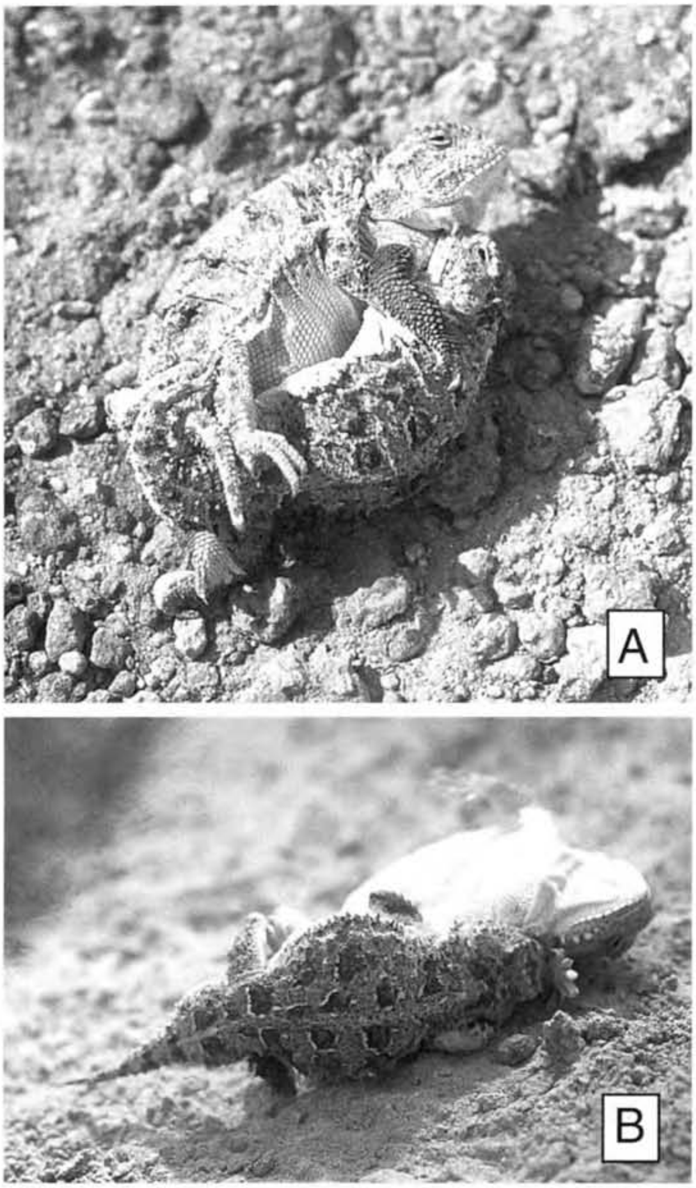

FIG. 1. Copulatory positions in *Phrynosoma douglassi*. A) Original position. B) position assumed when the male was reintroduced within close proximity of the female.

spines. Two details of my observation indicate that alternative explanations for the female's role in the behavior should be considered. First, the reaction of the female when the male was returned to her presence suggests active participation of the female in the mating process. Horned lizards occur in low densities and have large home ranges (e.g., Guyer 1991, *op. cit.*). Thus, opportunities to mate are likely to be infrequent, a condition that should make it equally advantageous for both sexes to participate actively in reproduction when the opportunity arises. Secondly, the female that I observed rarely initiated movements while in a copulatory position and seemed large enough to have avoided the male or righted herself during copulatory episodes. However, she was clearly less skittish than the male and relatively calm while on her back. Regardless of whether these behaviors are adaptive or not, the presence of this posture in *P. coronatum* and *P. asio*, two basal members of the *Phrynosoma* clade possessing large cephalic horns, and in *P. douglasii*, a derived species (Hodges and Zamudio 2004. Mol. Phylog. Evol. 31:961–971) possessing reduced cephalic horns, significantly broadens the phylogenetic distribution of this behavior within the genus.

SCELOPORUS UNDULATUS HYACINTHINUS (Northern Fence Lizard). **FIRE AVOIDANCE BEHAVIOR.** Few direct observations of reptile response to encounters with fire exist, and most involve animals seeking subterranean refugia (Russell et al. 1999. Wildl. Soc. Bull. 27:374–384). Similarly, Bishop and Murrie (2004. Herpetol. Rev. 35:397–398) reported two *S. undulatus* that each dug a burrow in the side of a dirt mound at the approach of a prescribed burn fireline in a sandhill community in Florida, USA. Here, I report a different response to fire in the same species in a similar situation in North Carolina.

At 1115 h on 27 September 1998, I observed an adult (ca. 60 mm SVL) male *S. u. hyacinthinus* basking on the trunk of a Longleaf Pine (*Pinus palustris*) about 1 m off the ground in a sandhill community at Sandhills Game Lands, ca. 14.5 km NW Wagram, Scotland Co. (34°59'32"N, 79°27'50"W [WGS84]; elev. ca. 108 m) during a relatively low-intensity prescribed burn. Besides *P. palustris*, Turkey Oak (*Quercus laevis*) and other scrub oaks, and Wiregrass (*Aristida stricta*) dominated this sandhill habitat. When the advancing flames reached the base of its tree, the lizard rapidly and steadily ascended the trunk until it passed beyond my view into the canopy (10+ m). It did not reappear during the 10–15 min. that I observed the fire. The lizard's retreat appeared to be in response to the smoke and/or heat. At 1230 h on 3 October 1998, I observed what appeared to be the same individual (based on sex, size, coloration, and similarly regenerated tail) basking in virtually the same spot on the same tree.

Based on the contrast with Bishop and Murrie (*op. cit.*), my observation suggests that *S. undulatus* employ different fire avoidance strategies depending on the situation.

Submitted by **JEFFREY C. BEANE**, North Carolina State Museum of Natural Sciences, Research Laboratory, 4301 Reedy Creek Road, Raleigh, North Carolina 27607, USA; e-mail: jeff.beane@ncmail.net

SCINCELLA LATERALIS (Ground Skink) **AQUATIC BEHAVIOR**. *Scincella lateralis* is a small, terrestrial skink common throughout woodlands of the southeastern United States (Conant and Collins. 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd ed., expanded. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.), When approached this species commonly scurries under logs, rocks, or other debris found on the substrate of the forests and glades where it is often found (Trauth et al. 2004. Amphibians and Reptiles of Arkansas. University of Arkansas Press, Fayetteville. 421 pp.). Here, we report aquatic behavior in *S. lateralis* from northwest Louisiana, USA.

At 0200 h on 2 June 2004 (T = 35°C, sunny), a *S. lateralis* (TL

= 5–6 cm) was observed basking on a log near a stream. The stream was ca. 10 cm deep, 1 m wide, and crossed the Sugar Cane Trail located at Caney Lakes Recreation Area in the Kisatchie National Forest, about 3 km N of Minden (Webster Parish; 32°67'49"N, 93°30'52"W [datum: WGS84], elev. 98.2 m). On approach, the skink dove into the water. Folding its limbs laterally along the body, it swam across the water surface using a lateral serpentine motion. It held its head above the water's surface until it emerged on the opposite side of the stream. As the skink approached within 3–4 cm of the stream's edge, it extended all four limbs, which quickly slowed its speed and cushioned its contact with the opposite shore. Upon contacting the edge of the stream, the skink quickly crawled out of the water and scurried under a large log located a few centimeters from the edge.

Aquatic behavior has been reported in this species (Akin and Townsend 1998. Herpetol. Rev. 29:43) and in other typically terrestrial lizards (*Crotaphytus collaris*: McAllister 1983. Herpetol. Rev. 14:11; *Cnemidophorus sexlineatus*: Trauth et al. 1996. Herpetol. Rev. 27:20–21; *Eumeces anthracinus pluvialis*: Means. 1992. *In* Moler [ed.], Rare and Endangered Biota of Florida. Vol. III., pp. 291., Univeristy of Florida Press, Gainesville; *Sphenomorphus quoyii*: Daniels 1985. Copeia 1985:1074–1077). Our report mirrors that of Akin and Townsend (1998), but adds detail of swimming behavior. Ability to flee predators by controlled swimming across small water bodies enlarges understanding of the repertoire of *S. lateralis* anti-predator behaviors.

Submitted by **MALCOLM L. McCALLUM** (e-mail: jamielmccallum@aol.com) and **CHRIS T. McALLISTER** (e-mail: chris.mcallister@tamut.edu), Department of Biological Sciences, Louisiana State University in Shreveport, One University Place, Shreveport, Louisiana 71115, USA, and Department of Biology, Texas A&M University-Texarkana, Texarkana, Texas 75505, USA.

SERPENTES

AIPYSURUS POOLEORUM (Shark Bay Sea Snake). **AVIAN PREDATION**. *Aipysurus pooleorum* is endemic to Shark Bay (Australia), although individuals have been found as far south as Perth. *Aipysurus pooleorum* was formerly treated as a subspecies of *A. laevis* from which they are distinguishable by smaller size, darker coloration, and tuberculate dorsal and ventral scales in males (Storr et al. 1986. Snakes of Western Australia. Western Australia Museum Publications. 187 pp.).

Around 0800 h in late November 2004 in the vicinity of Shark Bay (Redcliff, ca. 5 km N of Monkey Mia), a White-breasted Sea Eagle (*Haliaeetus leucogaster*) was spotted killing a snake on a sand bank ca. 800 m from shore at low tide. The snake was subsequently recovered and identified as a large female *A. pooleorum* (1360 mm TL). This record exceeds the maximum length previously known for this species (1140 mm TL; Heatwole 1987. Sea Snakes. The New South Wales University Press, Kensington, Australia. 85 pp.). Sea eagles (*H. leucogaster* and *Haliastur indus*) regularly eat true sea snakes. Sharks are also important predators (Heatwole et al. 1974. Copeia 1974:780–781). Other predators such as moray eels, groupers, sweetlip, and other fish, as well as the saltwater crocodile have been reported to eat true sea snakes in Australian waters (Heatwole 1987, *op. cit.*).

Submitted by **FABIEN AUBRET**, School of Animal Biology, M092, University of Western Australia, Perth, Western Australia 6009 Australia; e-mail: aubretf@cyllene.uwa.edu.au.

AGKISTRODON PISCIVORUS LEUCOSTOMA (Western Cottonmouth). **DIET.** *Agkistrodon piscivorus* is an abundant snake in the swamps and bayous of Louisiana and other southern states (Conant and Collins 1991. Reptiles and Amphibians Eastern Central North America. Houghton Mifflin, Boston, Massachusetts. 450 pp.). It is also an opportunistic predator known to actively hunt and consume a wide variety of prey items including carrion (Campbell and Lamar 2004. Venomous Reptiles of the Western Hemisphere. Cornell University Press, Ithaca, New York. 870 pp.). An adult male *A. p. leucostoma* was collected on 24 July 1994 at 1930 h from Spring Creek (2.9 km W of the jct of county roads 309A and 321), Bosque County, Texas, USA. The fluid-preserved whole specimen (deposited in the University of Texas at Arlington, UTA R-40717) was recently skinned and skeletonized. Measurements of the skin suggest the snake was ca. 570 mm SVL and its tail was ca. 100 mm. The stomach contained the following items: a partially digested juvenile softshell turtle (*Apalone* sp., 50 mm carapace length), one fish (Cyprinidae, 63 mm total length), one freshwater snail (Viviparidae, 7.9 mm total length), one Asian mussel (*Corbicula* sp., 15 mm x 11 mm), and the elytra from two beetles (Dytiscidae, 3 mm). Invertebrates have been documented from the stomach contents of *A. piscivorus* and are mostly considered to be the result of accidental ingestion (Gloyd and Conant 1990. Snakes of the *Agkistrodon* Complex: A Monographic Review. Society for the Study of Amphibians and Reptiles, Oxford, Ohio. 614 pp.). The turtle, mussel, snail, and beetles all represent new food records for *A. piscivorus*, although the mussel, snail, and beetles may have been accidentally or secondarily ingested.

Submitted by **CARL J. FRANKLIN,** The Amphibian and Reptile Diversity Research Center, Department of Biology, University of Texas at Arlington, Arlington, Texas 76019 (e-mail: Franklin@uta.edu).

CLELIA CLELIA (Mussurana, Zopilota). **DIET.** On 26 July 2004 at 1000 h we found a juvenile *Clelia clelia* within a stack of blankets on a shelf close to the floor inside Las Alturas field station (Las Tablas Protected Zone, San Vito de Java, Puntarenas, Costa Rica). The snake was induced (via palpation) to regurgitate a fledgling *Troglodytes aedon* (House Wren). The food item had been ingested head-first. *Clelia clelia* is mainly nocturnal but can be active during the day as well (Savage 2002. The Amphibians and Reptiles of Costa Rica. Univ. Chicago Press, pp. 527–529). The diet of *C. clelia* its well known throughout Costa Rica because of its ophiophagous habits. Savage (*op. cit.*) states that it feeds "primarily on other snakes including large pit-vipers ... but eats many lizards and mammals as well." This is the first record of *C. clelia* feeding on a bird of any kind. We suspect that the snake obtained its prey by foraging among nests in the roof of the building, but it is possible the snake opportunistically preyed on a fledgling that fell from one of these nests.

We thank E. Lindquist, V. Carmona, the Organization for Tropical Studies for facilitating research, H. Greene, N. Scott, R.

Henderson, and R. Timm for revising the manuscript.

CROTALUS BASILISCUS (Mexican West Coast Rattlesnake). **ENDOPARASITES.** Telford (1965. Japan. J. Exp. Med. 35:565–586) reported the occurrence of the nematode *Macdonaldius oschei* in *Crotalus basiliscus*. Herein, we report an additional species of nematode, *Hexametra boddaertii* and an acanthocephalan larva (oligacanthorhynchid cystacanth) in *C. basiliscus*.

Seventeen *C. basiliscus* (mean SVL = 957 ± 191 mm , range: 640–1280 mm) from the herpetology collections of the Natural History Museum of Los Angeles County (LACM) and the California Academy of Sciences (CAS), that had been collected between 1957–1976 from were examined. Methods for collecting helminths follow Goldberg and Bursey (2004. Herpetol. Rev. 35:75). One nematode (gravid female *H. boddaertii*) was found in LACM 7219, collected in Sinaloa, Mexico and one acanthocephalan (oligacanthorhynchid cystacanth) was found in CAS 147400, collected in Michoacán, Mexico. Both parasites were found in the body cavity. Prevalence (number infected snakes/number snakes examined x 100) for both *H. boddaertii* and the cystacanth was 6%. The *H. boddaertii* was deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland as USNPC 95371 and the acanthocephalan cystacanth as USNPC 95372.

Hexametra boddaertii was described from the colubrid *Mastigodryas boddaerti* occurrring in the West Indies (Kreis 1944. Rev. Suisse Zool. 51:227–252) and is restricted to viperid and colubrid snakes of the western hemisphere (Baker 1987. Occas. Pap., Mem. Univ. Newfoundland: 11:1–325). *Crotalus basiliscus* represents a new host record for *H. boddaertii* and Sinaloa, Mexico is a new locality record. Oligacanthorhynchid cystacanths have been reported in other North American viperid and colubrid snakes (Goldberg and Bursey 2004. J. Arizona-Nevada Acad. Sci. 37:83–84 and citations therein). *Crotalus basiliscus* represents a new host record for oligacanthorhynchid cystacanths and Michoacán, Mexico is a new locality record.

NATRIX TESSELATA (Dice Snake). **MARINE HABITAT**. A *Natrix tesselata* was observed on 7 April 2004 between Georgioupoli and Petres on the northern shore of the Greek island of Crete. No rivers reach the sea within several km of the sighting. A large number of sea urchins (*Paracentrotus lividus*) were observed at this locality, indicating that the local salinity level does not fluctuate much, as echinoderms have a low tolerance for salinity fluctuations (Boolootian 1966. Physiology of Echinodermata. John Wiley & Sons, New York. 846 pp.). Galan (2004. Herpetol. Rev. 35:71) reported *Natrix maura* from marine environs. Occurrence of this genus in pure seawater is not always due to habitat choice by the snakes, but can also be the result of passive drift (Lenk 2002. Zeitschrift für Feldherpetologie 9:221–223). Whether the *N. tesselata* we observed drifted from an estuary or more permanently inhabited this locality is unknown. It was found hiding below a rocky outcropping (fully submerged) in a tide pool less then 2 m from the sea, with only its head visible. The water of the tide pool was considerably warmer than that of the sea and contained small fish (Gobidae) as possible prey. It seemed in good health and did not show any signs of malnourishment.

Submitted by **ARIE VAN DER MEIJDEN** (e-mail: frog@arievandermeijden.nl) and **YLENIA CHIARI** (e-mail: ylenia.chiari@uni-konstanz.de), Lehrstuhl für Zoologie und Evolutionsbiologie, Department of Biology, P.O. Box M 618, University of Konstanz, 78457 Konstanz, Germany.

OXYBELIS AENEUS (Brown Vinesnake). **DIET.** *Oxybelis aeneus* is a diurnal, arboreal specialist reported to feed mostly on lizards, but also on frogs, birds, small mammals, and some insects (Henderson 1982. Amph.-Reptl. 3:71–80; Henderson and Binder 1980. Milwaukee Publ. Mus. Contr. Biol. Geol. 37:1–38; Savage 2002. The Amphibians and Reptiles of Costa Rica. Univ. of Chicago Press, Chicago. 934 pp.). Anoline lizards appear to form a large part of its diet (Keiser 1982. Cat. Amer. Amph. Reptl. 305:1–4).

On 26 June 2004, while videotaping frog behavior along a tributary of the Rio Marta, Cocle Province, Panama, I observed a *O. aeneus* (1020 mm TL) with a fish struggling in its mouth. I briefly videotaped the snake and its prey, and then continued to observe the snake for about 5 minutes (the video clip has been deposited in the Museum of Biological Diversity at Ohio State University and may be downloaded at: http://www.biosci.ohio-state.edu/~eeob/hetherington/Snake.WMV. The snake had seized the fish just behind the head and most of the fish's body extended out of the snake's mouth. The snake continuously and rhythmically swayed back and forth and occasionally jerked its head and neck in an attempt to re-position its prey for swallowing. After finishing videotaping the frogs, I captured the snake in order to identify the fish. During capture, the snake dropped the fish, a 52 mm long member of *Rivulus* (Poeciliidae; W. Bussing, pers. comm.), that appeared to be abundant in the stream.

When captured the body of the snake was not wet, suggesting that it had seized the fish while suspended above the pool rather than while swimming. The fish had numerous small lacerations just behind the head. The fish swam slowly and awkwardly within a plastic bag filled with river water and after ca. 5 minutes it showed no signs of respiration and appeared dead. Whether its death was related to envenomation by the snake, physical trauma, or oxygen deprivation could not be determined. However, the snake was

holding the fish in the posterior portion of its jaws when observed, so envenomation by this rear-fanged snake was possible.

To my knowledge, this is the first published report of an arboreal snake capturing a fish. The capture of the fish may have been an opportunistic feeding event by an individual hunting lizards and frogs. Many species of the anoline lizard genus *Norops* and a variety of frogs (e.g., *Eleutherodactylus* sp.) were observed among the vegetation and rocks alongside and in the stream. Vine snakes suspended over the stream could be well-positioned to capture such prey. Alternately, the snake might have been hunting specifically for these fishes in the shallow stream pools.

PITUOPHIS CATENIFER (Gopher Snake). **DIET**. The wide-ranging *Pituophis catenifer* has been documented to consume a large variety of prey items, including small mammals, birds, bird eggs, squamates, squamate eggs, frogs, frog eggs, turtle eggs, and insects (Rodríguez-Robles 2002. Biol. J. Linn. Soc. 77:165–183, and references therein). Rodríguez-Robles (*op. cit.*) examined the stomach contents of over 2,600 specimens of *P. catenifer* and reviewed published and unpublished dietary records, and found that mammals comprised the bulk of the prey items consumed (74.8%). Among these, only one record was of a carnivorous mammal (*Mustela frenata*).

On 13 August 2002 we collected an adult *Pituophis catenifer* (1370 mm SVL) on a rocky hillside in lower encinal woodland (ca. 1800 m elev.) on the eastern slope of the Sierra San Luis, Chihuahua, México. The following morning the snake regurgitated the mostly digested remains of a skunk (unidentified species). This represents the second record of predation upon a potential mammalian predator, and the first record of consumption of a skunk, by *P. catenifer*.

We thank R. Hibbitts and R. Queen for field assistance.

Submitted by **ROBERT W. BRYSON, JR.**, Department of Biological Sciences, University of Nevada, Las Vegas, 4505 Maryland Parkway, Las Vegas, Nevada 89154-4004, USA (e-mail: brysonjr@unlv.nevada.edu); and **MATTHEW INGRASCI**, 1719 Ogden Avenue, Lisle, Illinois 60532, USA.

THAMNOPHIS PROXIMUS RUBRILINEATUS (Western Ribbon Snake). **PREDATION.** *Thamnophis proximus rubrilineatus* is usually found in brushy habitats in close conjunction with aquatic situations (swamps, marshes, ponds, lakes, rivers, creeks, and desert springs) (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. University of Oklahoma Press. 332 pp.). The introduced fire ant (*Solenopsis invicta*) is widespread throughout most of the southeastern United States and is often found in the same habitats as *T. proximus*. When disturbed, *S. invicta* is well known for aggressive behavior hallmarked by several individuals simultaneously biting and stinging.

On 3 October 2004, at 1800 h, a juvenile *T. p. rubrilineatus* (183 mm SVL, 50 mm tail, 2.5 g) was found on the banks of a creek in Mills County, Texas (31°22.714'N, 098° 39.635'W, 598 m). The specimen was exposed when first observed and did not move when we approached nor did it resist capture. Instead the snake slowly moved the anterior portion of its body from side to side and opened its mouth. The mandibles of two *S. invicta* were found embedded in the badly damaged tail. The snake was euthanized and deposited in the University of Texas at Arlington (UTA R-52940). During previous outings in similar habitats in Hood and Palo Pinto Counties (Texas) one of us (CJF) encountered two juvenile *T. p. rubrilineatus* displaying the aforementioned lethargy and mouth gaping and both had noticeably injured tails. These observations also occurred in areas where *S. invicta* were active. Based upon these observations, it appears that *S. invicta* could negatively influence the survival of *T. p. rubrilineatus*.

FRANKLIN,** The Amphibian and Reptile Diversity Research Center, Department of Biology, University of Texas at Arlington, Arlington, Texas 76019, USA (e-mail: Franklin@uta.edu); and **DAVID C. KILLPACK,** 5924 Woodoak Drive, Dallas, Texas 75249, USA (e-mail: david@illuminationstudios.com).

THAMNOPHIS SAURITUS SAURITUS (Eastern Ribbon Snake). **MAXIMUM SIZE.** On 12 July 2004 we encountered a female *Thamnophis sauritus sauritus* (680 mm SVL, 1040 mm TL) near a small backwater slough (30.98°N, 87.92°W), in the Mobile-Tensaw Delta Wildlife Management Area, Baldwin County, Alabama, USA. The snake was beginning to consume a large female Bronze Frog (*Rana clamitans*). After the snake finished swallowing the frog (ca. 15 minutes) we captured and measured it. We captured a second female *T. s. sauritus* (685 mm SVL, 1021 mm TL) at approximately the same location on 5 July 2004. Both of these snakes exceed the maximum recorded total length of 1018 mm for *T. sauritus* (Ernst and Ernst 2004, Snakes of the United States and Canada. Smithsonian Institution Press, Washington and London. 680 pp.). Both snakes were marked and released as part of an ecological study.

We thank the Alabama Department of Conservation and Natural Resources and D. H. Nelson for assistance.

UROMACERINA RICARDINII (Vine Snake). **REPRODUCTION**. Highly arboreal snakes have a very slender body, long tail, and low mass which may enhance crypsis and facilitate support on small branches (Lillywhite and Henderson 1993. *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 1–48. McGraw-Hill, New York). However, slender body form may restrict reproductive output by limiting egg or clutch size (Marques 1998. Composição Faunística, História Natural e Ecologia de Serpentes da Mata Atlântica, na Região da Estação Ecológica Juréia-Itatins, São Paulo, SP. Ph.D. Dissertation. Univ. de São Paulo. 135 pp.). Data on relative reproductive effort in arboreal snakes are necessary to confirm this hypothesis (Lillywhite and Henderson, *op.*

cit.). Here, I report a reproductive event in *Uromacerina ricardinii*, a diurnal and arboreal snake occurring principally in Atlantic Forest in southeastern Brazil (Amaral 1978. Serpentes do Brasil. Melhoramentos Univ. São Paulo, Brazil. 246 pp.; Cunha and Nascimento 1982. Bol. Mus. Par. Emilio Goeldi, n.s. Zool. 113:1–9).

A gravid female (522 mm SVL, 415 mm tail, 28.5 g) was found on 9 November 2003 in Atlantic forest near Núcleo Santa Virginia (Parque Estadual da Serra do Mar, São Paulo, Brazil; 23°20'S, 45°08'W; ca. 810 m elev.) and maintained in captivity. On 12 November 2003, she laid five eggs between 2300–2400 h. These eggs averaged 24.8 ± 2.4 mm in length (range 22.4–28.8 mm), 10.2 ± 0.3 mm in diameter (9.9–10.8) mm, and 1.6 ± 0.1 g (1.5–1.8 g). Total clutch mass was 8.1 g and the female weighed 20 g after ovipositing, resulting in a relative clutch mass (RCM) of 40.5%. Relative reproductive effort (Lemen and Voris 1981. J. Anim. Ecol. 50:89–101), obtained by dividing the total clutch mass by female pre-oviposition mass, is 28.4%. The eggs were incubated in moist vermiculite (22–28°C). Hatching occurred between 25–28 January 2004 and the neonates were immediately weighed and measured. Four neonates (136.7 ± 4.7 mm SVL, range 131–142 mm; 103.5 ± 3.7 mm tail length, 102–105 mm; 1.12 ± 0.01 g, 1.12–1.14 g) hatched after an incubation period of 84–87 days. After twenty days the fifth egg was opened and a dead embryo was discovered. The female died seven days after ovipositing and was vouchered in the Instituto Butantan collection (IB69144).

Morato and Bernils (1989. Acta Biol. Leopol. 11:273–278) report a small clutch (three eggs) with oviposition in November and hatching in the end of January. Marques (1998, *op. cit.*) reported a gravid female with six eggs in November and two vitellogenic (follicles > 5 mm) females in August. Collectively, these observations suggest a seasonal reproductive cycle for *U. ricardinii*, with oviposition in the beginning of the rainy season (November–December) and hatching occurring in the end of the rainy season (February–March). *Uromacerina ricardinii* has the slender body typical of arboreal species but the RCM seems similar to that of terrestrial colubrids (Seigel and Ford 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 184–209. Macmillan Publ. Co., New York).

I thank O. A. V. Marques and M. T. Hartmann for reviews and FAPESP and CNPq for financial support.

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother 2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. SSAR Herpetol. Circ. 29:1–82, available online at <http://herplit.com/SSAR/circulars/HC29/Crother.html>; for Mexico as it appears in Liner 1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*. Herpetol. Circ. 23:1–113), LOCALITY (use metric for distances and give precise locality data), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author—curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Leviton et al. 1985, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology*, Copeia 1985[3]:802–832) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief), SUBMITTED BY (give name and address in full—spell out state or province names—no abbreviations).

Some further comments. This geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens which have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality color slide or photograph may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Color slides and photographs *must* be deposited in a university or museum collection along with complete locality data, and the color slide catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary) to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **Alan M. Richmond** (USA & Canadian records only); **Jerry D. Johnson** (Mexico and Central America, including the Caribbean Basin); **Indraneil Das** (all Old World records); or **Gustavo J. Scrocchi** (South American records). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Schmitz, A., and T. Ziegler. 2003. Geographic distribution. *Sphenomorphus rufocaudatus*. Herpetol. Rev. 34:385.

and

PATRICIA GOMEZ-ZLATAR
Department of Environmental Horticulture, University of Florida Gainesville, Florida 32611, USA

The contemporary increase in character data, especially the advent of rapid DNA sequencing, has provided taxonomists new tools for delimiting monophyletic groups. However, controversy concerning analytical techniques or data interpretation, as well as resistance to modifying established uses of names, may delay the acceptance of new phylogenies or taxonomic reclassifications. Additionally, new or revised classifications may take years to become established because of the time lapse between publication date and widespread use. Consequently, the proliferation of novel phylogenies and taxonomic revisions may prove confusing to comparative biologists, ecologists, and students.

The taxonomy of the lizard lineage Iguanidae (sensu lato Boulenger 1884; Camp 1923; Etheridge and de Queiroz 1988) has been both dynamic and controversial in the last 15 years. Since 1989, two familial taxonomic revisions (Frost and Etheridge 1989; Macey et al. 1997) and two expansions (Frost et al. 2001; Schulte et al. 2003), have been published for Iguanidae (sensu lato), and the current scientific literature is replete with conflicting taxonomies concerning this family. It may be bewildering to students when contemporary herpetology textbooks (e.g., Pough et al. 2001, 2004; Zug et al. 2001) report a particular classification scheme when other classifications might be more prominent in the literature. Further confusion ensues when the taxonomy of iguanid lizards in herpetological peer-reviewed journals often does not adhere to a consistent classification scheme—even in the same issue.

In an attempt to clarify the taxonomic record of Iguanidae (sensu lato), we summarize the taxonomic history and current status of the lineage. Additionally, because some authors of reclassifications have defended their taxonomic revisions by claiming that they have "widespread recognition and usage" (Frost et al. 2001: p. 13), we test this by analyzing nomenclature use in the scientific literature since 1990. Another interesting artifact of a dynamic taxonomic history is the time lapse between reclassifications and widespread adoption among biologists. To test this phenomenon, we statistically compare the use of different classifications (Boulenger 1884; Frost and Etheridge 1989; Frost et al. 2001; Macey et al. 1997) in terms of their citation frequency per year and by journal type.

Taxonomic Summary.—Iguanidae (sensu lato Boulenger 1884; Camp 1923; Etheridge and de Queiroz 1988) is the largest (ca. 51 genera and 908 species; Pough et al. 2001) and most widely distributed family of lizards in the Western Hemisphere. Iguanids are found throughout the Americas including the West Indies and Galápagos Archipelago. Two extralimital genera occur on Madagascar and the Comoro Archipelago, and another in the Fiji and Tonga Islands (Etheridge and de Queiroz 1988). The disjunct distribution of the family was thought to be a potential artifact of paraphyly (Frost and Etheridge 1989) because morphological evidence of either monophyly or paraphyly for Iguanidae* was ambiguous, and the family was thus considered a metataxon (denoted with an asterisk; Estes et al. 1988).

Etheridge and de Queiroz (1988) were the first to attempt a phylogenetic reconstruction of iguanid lizards using outgroup comparisons and modern character-based phylogenetic methods. Their analysis of morphological characters suggested that iguanid species could be placed in one of eight major groups (Anoloids, Basiliscines, Crotaphytines, Iguanines, Morunasaurs, Oplurines, Sceloporines, Tropidurines). However, they acknowledged that they could not identify any synapomorphies for Iguanidae (sensu lato) indicating that it may be paraphyletic.

Based on a cladistic analysis of morphological characters, Frost and Etheridge (1989) did not find evidence of monophyly for Iguanidae (sensu lato). They also failed to resolve the intergroup relationships within iguanids, but claimed that their data supported monophyly for the previously recognized informal groups of Etheridge and de Queiroz (1988). With intent to reform named but potentially misleading groupings, they recognized as families (sedis metabilis) the largest historical groups that were consistent with the strict consensus tree generated by their phylogenetic analysis of Iguania (Table 1). The iguanines, consisting of the extant genera *Amblyrhynchus* and *Conolophus* (Galápagos Islands), *Cyclura* (West Indies), *Brachylophus* (Fiji), *Dipsosaurus*, *Sauromalus*, *Ctenosaura*, and *Iguana* (southwestern North America, the latter two extending south to Central America and Northern South America, respectively) were elevated to Iguanidae (sensu stricto). This cladistic reanalysis, along with the new taxonomy for Iguanidae, proved highly controversial because of its principles, methodology, interpretations, and its direct challenge to deeply entrenched informal nomenclature (see Lazell 1992; Schwenk 1994; Frost and Etheridge 1993). Nevertheless, their study proved instrumental in providing workable hypotheses for subsequent systematic investigations.

Macey et al. (1997) performed a phylogenetic analysis of Iguanidae (sensu lato) and Acrodonta (Agamidae + Chamaeleonidae) using mtDNA sequences and the morphological data of Frost and Etheridge (1989). Analyzed separately, the morphological and molecular data suggested different phylogenetic hypotheses with the morphological data recovering a weakly paraphyletic Iguanidae (sensu lato), and the sequence data recovering a strongly supported monophyletic Iguanidae (sensu lato). The monophyly of the family, however, also was supported by (1) separate analyses of protein-coding and t-RNA-coding subsets of the DNA sequences; (2) analysis of amino acids from protein-coding regions; (3) analysis of the total DNA sequence data with silent transitions removed from the protein-coding sequences; and (4) use of transversion parsimony on the total DNA sequence data. Although their sampling was not adequate to establish monophyly of Frost and Etheridge's (1989) eight families, these authors sug-

TABLE 1.—Taxonomic names for groups of the family Iguanidae (sensu lato Boulenger, 1884) respectively proposed by Etheridge and de Queiroz (1988) for informal groups, Frost and Etheridge (1989) for families and subfamilies, Macey et al. (1997) for subfamilies, Frost et al. (2001) for families and subfamilies, and Schulte et al. (2003) for an unranked taxonomic scheme. Names correspond to others in successive columns. Clarification is provided where names may be ambiguous.

Etheridge and de Queiroz (1988)	Frost and Etheridge (1989)	Macey et al. (1997)	Frost et al. (2001)	Schulte et al. (2003)
Anoloids	Polychridae	Polychrinae	Polychrotidae[e,f]	Polychrotinae*[p]
			Leiosauridae[g]	Leiosaurini[k]
			Leiosaurinae[h]	Leiosaurae[l]
			Enyaliinae[i]	Anisolepae[m]
				Anolis[n]

	Liolaeminae[c]		Liolaemidae	Liolaemini
	Tropidurinae[d]		Tropiduridae[j]	Tropidurini

[a] Containing the subfamilies Leiocephalinae, Liolaeminae, and Tropidurinae.
[b] Restricted to *Leiocephalus*.
[c] Contains *Ctenoblepharys*, *Liolaemus*, and *Phymaturus*. See Frost and Etheridge (1989) for comments.
[d] Contains "*Ophryoessoides*," *Plica*, *Proctotretus*, "*Stenocercus*," *Strobilurus*, *Tapinurus*, "*Tropidurus*," *Uracentron*, and *Uranoscodon*. See Frost and Etheridge (1989) for comments.
[e] Restricted to *Anolis* and *Polychrus*.
[f] Spelling corrected (Böhme 1990; pers. comm.) after the wrong name formation was applied to the genitive case of Polychrotos in Frost and Etheridge (1989).
[g] Containing the subfamilies Enyaliinae and Leiosaurinae.
[h] Contains "*Leiosaurus*" (see Frost et al. [2001] for taxonomic discussion), *Diplolaemus*, and *Pristidactylus*.
[i] Contains *Enyalius*, and the para anoles (*Anisolepis* and *Urostrophus*).
[j] Excluding the former subfamilies Leiocephalinae and Liolaeminae of Frost and Etheridge (1989).
[k] Corresponds with Leiosauridae of Frost et al. (2001).
[l] Corresponds with Leiosaurinae of Frost et al. (2001).
[m] Corresponds with Enyalinae of Frost et al. (2001).
[n] *Anolis* of Jackman et al. (1999) including *Chamaeleolis*, *Chamaelinorops*, *Norops*, and *Phenacosaurus*.
[o] *Polychrus* of Peters and Donoso-Barros (1970; including *P. peruvianus* [Noble 1924]).
[p] Monophyly is statistically equivocal based on the combined morphologic and molecular data of Schulte et al. (1998), thus these authors recommend retaining the subfamily as a metataxon(*) for taxonomic convenience.

gested a return to the classic taxonomy (sensu Boulenger 1884), with the eight major lineages within Iguanidae (sensu lato) recognized as subfamilies (Table 1).

Frost et al. (2001) examined the relationships within Polychrotidae (sensu Frost and Etheridge 1989) using both molecular and morphological data. Data from the combined analysis suggested that the Polychrotidae, as hypothesized by Etheridge and de Queiroz (1988) and Frost and Etheridge (1989), is not monophyletic because Corytophanidae (sensu Frost and Etheridge 1989) was nested within it. Substantial evidence also suggested that leiosaurs and the austral para-anoles formed a monophyletic group, which was elevated to Leiosauridae containing the subfamilies Leiosaurinae and Enyaliinae. Frost et al. (2001) suggested resurrecting the name Pleurodonta (Cope 1864) for the monophyletic group formally known as Iguanidae (sensu lato) because such a classification provided symmetry with its sister taxon, Acrodonta (Cope 1864). The authors stated further that if pleurodont iguanian monophyly is falsified or found dubious (under the approach advanced by Macey et al. 1997), the need for subsequent major changes to the taxonomy would be nullified.

Frost et al. (2001) also considered the results of Macey et al. (1997) and acknowledged having no scientific reason to dispute their reclamation of Iguanidae (sensu lato), yet suggested that their family-group names (sensu Frost and Etheridge 1989) had achieved widespread acceptance and usage. Frost et al. (2001: p. 13) also suspected that additional investigations into the fossil record would

further cloud phylogenetic evidence for monophyly of the Iguanidae (sensu lato), claiming that "the canon of monophyly is not violated," and that their subjective choice of ranks (Table 1) would lead to the least confusion, facilitate progress, and impart the best current hypothesis for understanding the phylogeny of the group.

Most recently, Schulte et al. (2003) used previously published morphological characters (in Frost and Etheridge 1989; Schulte et al. 1998) and molecular data (Macey et al. 1997; Schulte et al. 1998, 2000), with new molecular sequences to reexamine relationships among the major lineages of iguanid lizards. The monophyly of Iguanidae (sensu lato) was strongly supported by the molecular and combined data sets. Schulte et al. (2003) advocated recognizing Iguanidae (sensu lato) as a monophyletic group because monophyly was strongly supported by their data and with previous analyses of combined morphological and sequence data, as well as sequence data alone (Harris et al. 2001; Macey et al. 1997; Schulte et al. 1998). These authors proposed an unranked taxonomic scheme for all the supraspecific taxa of Iguania, whereas they associated Iguanidae with the clade composed of all eight major groups defined by Etheridge and de Queiroz (1988), which correspond with Pleurodonta of Frost et al. (2001; Table 1).

Literature-Use Analysis.—We analyzed the frequency of use for Iguanidae (sensu lato) from 1990 through 2004 by performing a general topic search in titles, abstracts, and keywords for the terms "Corytophanidae or Corytophaninae or Crotaphytidae or Crotaphytinae or Enyaliinae or Hoplocercidae or Hoplocercinae or Iguanidae or Iguaninae or Leiocephalidae or Leiocephalinae or Leiosauridae or Leiosaurinae or Liolaemidae or Liolaeminae or Opluridae or Oplurinae or Phrynosomatidae or Phrynosomatinae or Polychridae or Polychrinae or Polychrotidae or Tropiduridae or Tropidurinae" using the Thomson ISI–Web of Science® (WOS) Internet search engine. The WOS search engine was used because of its large database and convenience over other electronic means of searching the literature. We also performed a separate search from 1990 through 1999 using the Caribbean Journal of Science (CJS) website because the Iguanidae (sensu lato) is represented abundantly in the region and pre-2000 citations of this journal are not included in the WOS. A post-hoc search for Polychrotinae in WOS yielded only three citations within the study time frame, none of which were excluded from the previous search.

Citations were categorized as adopting one of the following taxonomic schemes: Boulenger (1884), Frost and Etheridge (1989), Frost et al. (2001) or Macey et al. (1997). Papers were examined first hand if taxonomic use was ambiguous from titles or abstract listing in the WOS or CJS results. Of these, papers that did not reference a specific family, subfamily, or taxonomic authority were not included in the analyses. Because extant iguanine lizards (sensu Etheridge and de Queiroz 1988; *Amblyrhynchus*, *Brachylophus*, *Ctenosaura*, *Conolophus*, *Cyclura*, *Dipsosaurus*, *Iguana*, and *Sauromalus*) cited as "Iguanidae" could be attributed to either Boulenger (1884) or Frost and Etheridge (1989), these were also excluded unless authors stated the taxonomy followed in their paper.

In some instances, the classification schemes used in post-1997 articles could pertain to one of two classifications. For example, a 1999 article assigning *Anolis* to Iguanidae could fall under either Boulenger (1884) or Macey et al. (1997). In these cases, we assumed the authors followed the most recent revision and scored citations as Macey et al. (1997). Additionally, post-2001 references involving lizards in clades with the same taxon names as in Frost and Etheridge (1989) (e.g., Phrynosomatidae, Polychrotidae, Tropiduridae, etc.) also could be included under Frost et al. (2001). In these cases, we also assumed that the authors intended to use the most-recent revision, so we scored these references as Frost et al. (2001). To analyze journal-specific trends in taxonomic use, citations also were categorized by one of four journal types: (1) Biology/Ecology, (2) Herpetology, (3) Medical/Parasitology, and (4) Molecular/Systematics.

We used chi-square tests of independence to test for trends between taxonomic scheme and their frequency of citation by year and journal category. If tests were significant, we described trends by comparing individual cell-observed frequencies to cell frequencies expected under a hypothesis of independence. Trend description was limited to cells that provided a large contribution (i.e., large individual chi-square value) to the overall significance of the chi-square (SAS OnlineDoc®, V. 8, Cary, NC: SAS Institute Inc. 1999). We used exact tests when 25% or more of the expected cell counts in a contingency table were less than five.

Results of Literature-Use Analysis.—Of the 520 articles found by our combined WOS and CJS literature search, 428 (representing 89 journals) were used in our analysis. From 1990–1997, use of the two available taxonomies was not statistically independent by year (χ^2 test, $P < 0.0001$; Table 2). From 1990–1992, chi-square values for individual cells revealed that a greater number of authors than expected (if random) followed the taxonomy of Boulenger (1884), whereas fewer than expected adopted that of Frost and Etheridge (1989). From 1993–1997, the opposite trend emerged as a smaller number of authors used the classification of Boulenger (1884) and more than expected adopted that of Frost and Etheridge (1989; Table 2).

From 1998–2001, we assigned 17 papers to Iguanidae sensu Macey et al. (1997) that might otherwise have been classified as following Boulenger (1884). During this period there was no sig-

TABLE 2. Observed and expected observations followed by individual cell chi-square values for the competing Iguanidae (sensu lato) taxonomies from 1990–1997. Note the change in observed relative to expected values between classifications in 1993 (in bold).

Taxonomy	χ^2 parameters	1990	1991	1992	**1993**	1994	1995	1996	1997

	Cell χ^2	**1.0385**	0.0185	**1.2308**

nificant trend in taxonomic use (Fisher's Exact test, $P = 0.77$) and cell chi-square values indicate that, according to our scoring method, the two competing taxonomies (Frost and Etheridge 1989; Macey et al. 1997) were used as frequently as expected in proportion to the number of times that they were used throughout this four-year period. Although no significant trend was found, more authors published papers adhering to the taxonomy of Frost and Etheridge (1989; Fig. 1A).

From 2002–2004, 30 papers were assigned to Frost et al. (2001) despite being potentially attributable to Frost and Etheridge (1989). Likewise, 11 papers were assigned to Macey et al. (1997) despite being potentially attributable to Boulenger (1884). One paper adhering to the taxonomic expansion of Schulte et al. (2003) was found in 2004. During this period, the three available taxonomies (Frost and Etheridge 1989; Frost et al. 2001; Macey et al. 1997) were not used as frequently as expected (χ^2 test, $P = 0.04$; Table 3) relative to the number of times that each was used throughout the sample years. In 2002, chi-square values for individual cells revealed that more authors than expected adopted the taxonomy of Frost and Etheridge (1989), whereas fewer than expected adopted that of Frost et al. (2001). In 2004, the opposite trend emerged with fewer authors using the taxonomy of Frost and Etheridge (1989) and more than expected adopting that of Frost et al. (2001). The taxonomy of Macey et al. (1997) was used as frequently as expected throughout this sample period (Table 3). In addition to the trends noted above, overall more papers were published adhering to the taxonomy of Frost and Etheridge (1989) and Frost et al. (2001) than to Macey et al. (1997; Fig. 1A).

The four competing taxonomic classifications used in publications were not independent of journal category (χ^2 test, $P = 0.0004$; Table 4). Cell chi-square values illustrate that under a hypothesis of independence, Boulenger (1884) was used more than expected in biology/ecology journals, but less than expected in herpetology and molecular/systematics journals. Both Frost and Etheridge (1989) and Frost et al. (2001) were represented more than expected in herpetology journals, whereas Frost et al. (2001) was used more than expected in parasitology/medical journals, but less than expected in biology/ecology journals. The taxonomy of Macey et al. (1997) was used less than expected in herpetology journals, but more than expected in molecular/systematics journals (Table 4).

Literature-Use Discussion.—Our results reveal a three-year time lapse before the reclassification of Frost and Etheridge (1989) became the most commonly used taxonomy in the scientific literature. Frequency data indicate that the taxonomy of Frost and Etheridge (1989) peaked in 1996, representing 84% of publications that year (Fig. 1B). This lag could be an artifact of the highly controversial nature of the reclassification (see Schwenk 1994), the result of less advanced communication technology (i.e., email and Internet), or the often-lengthy lag from manuscript acceptance to time of publication.

The lack of a statistical trend favoring any particular classification scheme from 1998–2001 suggests that the taxonomy of Macey et al. (1997) was met originally with acceptance. Interestingly, a trend was uncovered post-2001 indicating a transition from Frost and Etheridge (1989) to Frost et al. (2001), whereas the taxonomy of Macey et al. (1997) was represented in the literature as expected (Table 3). This suggests a loyal following of the Frost and Etheridge (1989) taxonomy and a willingness to adopt the new Frost et al. (2001) taxonomy within two years.

Iguanids are models for comparative behavioral, ecological, morphological, and physiological studies, which is reflected in the journal data. From 1990–2004, a total of 89 journals published

TABLE 4. Observed and expected observations followed by individual cell chi-square values for the competing Iguanidae (sensu lato) taxonomies for the four journal categories. Cells that have the largest influence on the chi-square value are in bold.

Journal Category	χ^2 parameters	Boulenger (1884)	Frost and Etheridge (1989)	Macey et al. (1997)	Frost et al. (2001)

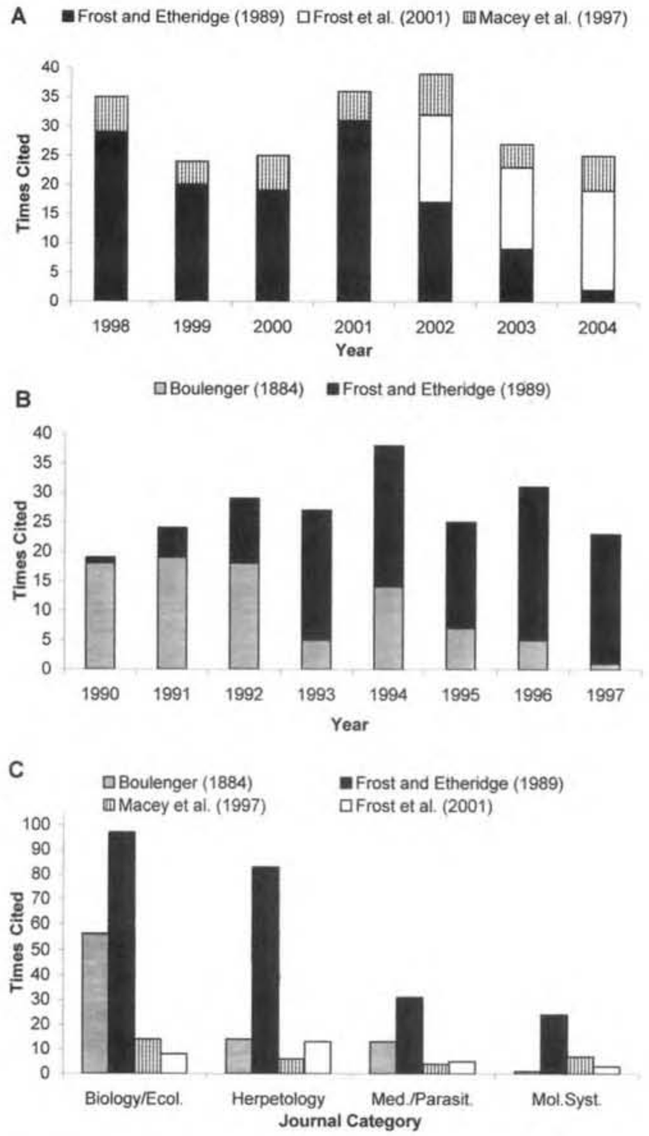

FIG. 1. (A) Number of citations from 1998–2004 referencing the three possible classifications. Post-1997 articles (N = 28) were defaulted to Macey et al. (1997) despite being potentially attributable to Boulenger (1884). Post-2001 references (N = 30) were attributed to Frost et al. (2001) despite being potentially attributable to Frost and Etheridge (1989). See text for details. (B) Number of citations from 1990–1997 following Boulenger (1884) and Frost and Etheridge (1989). (C) Number of citations from 1990–2004 adhering to the four taxonomic possibilities and stratified by journal category.

articles referencing iguanid taxonomy. Many of these journals are biology/ecology oriented and our data demonstrate a higher reference usage of the older monophyletic Iguanidae (sensu Boulenger 1884) taxonomy within these journals, and a lower than expected usage in herpetology journals. The literature summarized here suggests that the discrepancy may be due to greater awareness of the most current classification by manuscript reviewers and editorial boards. It is interesting that articles published in herpetology oriented journals appear to be favoring more often the taxonomy of Frost and Etheridge (1989) and the more recent Frost et al. (2001) over the Macey et al. (1997) taxonomy and its subsequent modifications (e.g., Schulte et al. 1998, 2003) (Fig. 1C; Table 4).

Conflicting opinions exist in the herpetological community concerning the usage of the taxonomic revisions and subfamily classifications proposed by Frost and Etheridge (1989) and Macey et al. (1997), respectively. Frost et al. (2001: p. 13) defended the eight-family taxonomy of Frost and Etheridge (1989) by claiming that it had "widespread recognition and usage," whereas Schulte et al. (2003: p. 415) countered that "The eight-family taxonomy of Frost and Etheridge was proposed in 1989, was never fully accepted, and subsequently rejected by Macey et al. (1997)." Our literature-use analysis indicates that the taxonomy of Frost and Etheridge (1989) has been supported by continued widespread use four years subsequent to publication (Fig. 1B) despite not being featured in a herpetology textbook (Zug et al. 1993) until nine years after publication (Pough et al. 1998). Although the Macey et al. (1997) classification scheme of a monophyletic Iguanidae with multiple subfamilies is featured in recent herpetology textbooks (e.g., Pough et al. 2001, 2004; Zug et al. 2001), our data indicate that it has not been adopted as widely in the scientific literature as has Frost and Etheridge (1989) or even the more recent Frost et al. (2001) taxonomic recommendations (Fig. 1A). However, we recognize that more time may be required to detect taxonomic influences educed by these recent textbooks especially in light of several taxonomic choices.

A question worth addressing concerns the lack of widespread adoption of the eight-subfamily Macey et al. (1997) phylogenetic reclamation of Iguanidae (sensu lato). Macey and colleagues published compelling evidence for the clade, which was supported subsequently by Schulte et al. (1998), Harris et al. (2001), and Townsend et al. (2004). Furthermore, Frost et al. (2001) acknowledged having no scientific reason to dispute the recovery of Iguanidae (sensu lato). Therefore, it is surprising that the Macey et al. (1997) subfamily taxonomy is underrepresented in the literature, whereas the more recent Frost et al. (2001) revision has received broader acceptance.

Conclusions.—In biological nomenclature, communication is most effective if taxon names are universal and stable. The association between a name and a taxon should be unequivocal; all biologists should use the same name for the same taxon, and a name should not designate different taxa, or a taxon assigned different names at different times (de Queiroz and Gauthier 1994). Consequently, researchers should exercise caution, evaluate alternative nomenclature, and adopt classifications that promote stability or accurate testing of hypotheses (K. de Queiroz, pers. comm.). Although differences of opinion facilitate debate and research, inconsistent use of nomenclature can promote spurious interpretations of comparative data across higher taxa. Minimally, authors should therefore reference their choice of classification schemes, especially when testing evolutionary hypotheses.

Acknowledgments.—We thank W. Judd and J. Reiskind for initiating the taxonomic summary. We thank A. Alberts, K. de Queiroz, K. Dodd, R. Espinoza, R. Etheridge, R. Powell, and four anonymous reviewers who provided valuable comments on the manuscript.

Habitat Use and Activity Patterns of Two Green Ratsnakes (*Senticolis triaspis*) in the Chiricahua Mountains, Arizona

WADE C. SHERBROOKE
Southwestern Research Station, American Museum of Natural History
P.O. Box 16553, Portal, Arizona 85632, USA
e-mail: wcs@amnh.org

Although *Senticolis triaspis* is distributed from Costa Rica to the southwestern United States its behavior and activity patterns are not well-documented (Price 1991; Schulz 1996; Stebbins 2003). Here I report on movements, use of habitat, and behaviors of two females (*S. t. intermedia*) during radiotelemetry studies in a Sierra Madrean mountain range in southeastern Arizona, at the northern limit of the species' range.

Materials and Methods.—On 21 July 1994, an adult female *Senticolis triaspis* (Snake #1) was collected at 1900 h on Cave Creek Canyon Road (USFS Road #42) between Stewart and Sunny Flat Campgrounds (elevation 1540 m), Chiricahua Mountains, Coronado National Forest, Cochise County, Arizona, USA. The snake measured 953 + 232 mm (SVL + tail length) and weighed 182 g (Pesola™ scale). On 23 July the snake was anesthetized with isoflurane (Forane™) to allow surgical implantation of a Holohil™ transmitter BG-2G (2.8 g) in the coelomic cavity (Reinert and Cundall 1982). The snake was released the following morning (0900 h), 30 m S of the collection point. On 24 August 1999, a second adult female *S. triaspis* (Snake #2; 690 + 162 mm, 82 g) was collected at 0900 h on the same road, but 100 m below Cazier Bridge (elevation 1616 m). Surgical procedures for implanting a Holohil™ transmitter BD-2G (1.85 g) and tracking were as with Snake #1, except the anesthesia was sevoflurane (Ultane™). Snake #2 was released, at 0820 h on 25 August 1999, 30 m S of where collected. Both snakes were subsequently radio-tracked using a Telonix™ receiver (TR-2) and antenna (RA-2A). Distances between sites were measured with a 50 m tape (except as noted), boulder and tree dimensions and heights were determined with the aid of tape and extendable measuring pole, sites were photographed (all 1994, most 1999–2000) and marked with flagging tape, and observations of visible snakes were aided by 9×35 binoculars. Sites were only visited during daylight hours. Searches were more frequent in the afternoon than in the morning (116 versus 43) and the number of hours in a day during which searches occurred were more numerous in the afternoon (morning, 0600–1200 h = 6 h; afternoon, 1201–2100 h = 9 h). Each time a snake was located I, or an assistant, recorded the date, time (MST), distance and direction (compass points) from last encounter location (if changed), occurrence of rain within the last 24 h period (at site or from records at Southwestern Research Station, 4 mi SW Por-

tal; < 5 km from tracking sites), site habitat and microhabitat notations, and air temperature (AT; with a shaded rapid-adjusting mercury thermometer (Schultheis™ 0–50°C; Weber & Miller, Queens, New York).

The entire field site occurs within a Madrean Evergreen Woodland (Brown 1982) community. The Cave Creek riparian community includes Arizona Sycamore (*Platanus wrightii*) and Arizona Walnut (*Juglans major*). Canyon terraces and slopes facing north and northwest support an oak-juniper-pine community, while south- and southeast-facing slopes are characterized by bare rock slides with islands of shrub/oak vegetation. Steep canyon walls are lichen-covered rhyolite lava (Oligocene), with many rock outcrops and sheer cliffs along the upper portions, and Holocene gravels fill Cave Creek (Drewes et al. 1995).

Results.—Snake #1 was located 79 times between 24 July and 3 October 1994 at 13 distinct sites. Six of these sites were subterranean refuges; three were occupied for periods of > 21, > 19, and > 8 days (beneath boulders; 540 × 190 × 320 cm, 710 × 475 × 366 cm, 465 × 280 × 228 cm, respectively), and three were occupied >2<10 days. During 72 days Snake #1 was observed active above ground five times (three times at underground location sites) and was located at ten subterranean sites. Rock dimensions at other measured underground sites were as follows: 90 × 70 × 30 cm to 27 × 30 × 10 cm, 135 × 70 × 30 cm, 313 × 96 × 84 cm, 88 × 96 × 84 cm, and 80 × 55 × 60 cm. The total measured distance moved was 573 m, plus an unmeasured distance (when the animal was temporarily lost) estimated (from a topographic map) to be over a kilometer. Thus, the estimated total straight-line distance traveled was 1573 m, for a mean distance of 161 m between locations. Omitting the estimated 1 km movement, the mean distance between locations was 48 m (range = 2–215 m).

On 25 July Snake #1 was observed (1430 h) sunning on a 4 cm diameter dead branch at 4 m high in a *Quercus arizonica*. On 5 September it was 1 m from a massive boulder underground-site in shade, between 1350–1514 h (AT 30°C); an accumulation of acorns and a rodent hole had been noted earlier at the base of this boulder. The snake retreated beneath the boulder where it had been since 17 August. It moved by the following afternoon, following rain on 3 and 5 September and a stay of >19 days. On 6 September (1530 h; AT 30°C) the snake was on the ground partially beneath a small log, head up, with <5% of its body in the sun. Later it was located (1700 h; AT 30°C) stretched out in a small < 1 m tall *Quercus hypoleucoides* that had been exposed to the setting sun's rays. The snake descended and proceeded up slope; forward motion was accomplished by a series of short advances of the head, with each advance followed by a slightly shorter retreat (slow-motion jerky advances). At 1745 h the snake stopped forward locomotion when discovered by a juvenile Mexican Jay (*Aphelocoma ultramarina*). The bird departed after 2–3 min when other members of its flock were not recruited by its calls near the snake. At 1824 h visual contact was again lost as the snake passed a boulder flanked by dense shrubs. After about 5 min, a deer mouse (*Peromyscus* sp.) ran up and over the boulder, escaping into vegetation. Examination revealed a rodent hole next to the upper end of the boulder. Apparently the snake entered the hole and caused the mouse to flee. Subsequent radio signals (8 daily visits through 14 September) suggested underground movements to positions 3–4 m from the boulder. On 13 September the snake was again seen at an edge of this boulder (AT 31°C), immediately retreating into the rodent hole. Within two days it departed the site, occupied for >8<10 days.

Snake #1 occupied ten subterranean sites, of which seven were inhabited for less than 27 h 10 min, and three were respectively inhabited for 21 days, 19–20 days, and 8–10 days. Thus the snake spent 48–51 of the 72 days (66–71%) in long-term sites. The three short-term subterranean sites (>2<10 days) bring the total occupation days for these sites up by at least six days. The snake's positions were determined repeatedly (2–34 times) at five sites. At three sites (duration of occupancy >11.5<24.5 h; >11.5<25.5 h; >22 days) no positional changes were recorded. Additionally (two sites), its position was determined 34 times (>21 days occupancy) with internal site movements of 1 (7), 3 (1), or 0 (25) m, and 9 times (>8<10 days occupancy) with internal site movements of 1 (1), 3 (2), 4 (1), and 0 (4) m.

On 23 September Snake #1 was located 20 m to the south of a major ridge it had crossed. This drainage translocation placed the snake in a separate basin of Cave Creek on a south-facing slope, whereas its former activity was on north-facing slopes. At two subsequent sites, Snake #1 was located on a steep talus slope, lacking vegetation except for isolated islands, composed of very angular rocks (surface 5 × 20 cm; some larger, 40 × 70 cm). Such slopes dominated the landscape.

In three of thirteen location changes (periods between encounters >24 h) time of day is unknown, and in two cases both nocturnal and diurnal periods occurred between observations. But in eight of the site moves, snake site-location times were of sufficient frequency to provide data on dial movements, all diurnal or crepuscular. Three diurnal moves could not be limited to morning or afternoon (0900–1440 h; 0635–1430 h; 0955–1920 h). One move occurred in the morning (0650–1120 h). And, four of the moves occurred in the afternoon (1440–1990 h; 1430–1920 h; 1530–1700 h; 1722–1824 h).

Snake #1 vacated one site within a few hours after rain. Five rain events occurred while the snake was at the subsequent site, but it did not move until six days after the last rain. Then it vacated its new site after rain the previous night. Later, three rain events occurred while the snake was at a long-term site, but it only moved two or three days after the last rain.

Following release in the canyon bottom, Snake #1 remained in the lower areas (24 July–15 August) before beginning a multiply-site climb in a southeasterly direction over largely northwest-facing slopes (6 September–14 September). From 14 to 23 September the snake's location was not determined as it crossed over a very steep ridge to descend onto a south-facing slope (23 September-3 October). Search efforts between 7 October and 10 November were unsuccessful, and the study was terminated.

Mean daily movement of Snake #1 over the study period, between 24 July and 3 October, was 21.8 m/d. During the period 24 July through 14 September the snake moved 350 m, 6.6 m/d over 53 days. It then moved an estimated 1000 m or more over 10 days, increasing its elevation ca. 500 m. Once relocated to a south-facing slope, the snake then moved twice, 215 and 8 m, during 11 days, for a mean distance of 20.3 m/d. Between 14 September and 3 October (21 days) it moved 223 m plus 1 km, estimated (1223 m; 78% of the total moved, 1573 m), 37 m/day.

Snake #2 was located 80 times (usually daily, twice on five days,

except when hibernating) over 147 days between 25 August 1999 and 18 January 2000, after which the transmitter signal failed. Of 31 sites, nine were occupied on multiple visits indicating the presence of the snake for, >24 h , > 32 h, >22 h, >19 days, > 7 days/20 h < 10 days, >22 h, > 45 h, >30< 36 days, >41 days. Thus four sites were occupied < 48 h, and four were occupied for periods of about eight to >41 days.

Observation of the snake above ground allowed determination of activities at nine sites: 3 September (1425 h), 1 m up the west side of a *Yucca schottii*, <5% of body in the sun, not moving (AT 26°C); 4 September (1115 h) immobile inside a rock crevasse 6 m above ground level (AT 24°C); 9 September (1515 h) elevated 10 cm in branches of a low tree, 20% in sun (AT 28°C); 10 September (1700 h) 2 m above ground in *Pinus leiophylla* (AT 28°C); 11 September (1715 h) 15 cm above ground in branches of *Quercus hypoleucoides*, 0% sun (AT 25°C); 8 October (1450 h) coiled on the ground under a dead oak stump (0% sun); 9 October (0835 h) inside a 20 cm opening under a rock (0% sun; AT 14°C); 10 October (1335 h) exposed on leaf litter, crawling (26°C); 21 October (1520 h) in creek bed where it was apparently undergoing a lengthy move northward, 106 m from last site and 24 m to next recorded site.

In the creek bed it was watched (1520–1710 h; AT 18–15°C) as it moved 12.5 m, with 3–5 min periods of non-movement, apparently in response to the presence of the observer. Snake movements were similar to those observed with Snake #1 (6 September 1994): moved with jerky forward-backward movements, head back and forth in short jerky motions, but tail moved at slow, relatively uniform pace.

The subterranean position of Snake #2 was determined multiple times at nine sites. Distance of short within-site changes in location were noted (dates and duration of site occupancy): (25–26 August; > 24 h), 3, 4, and 2 m; (27–28 August; >34 h) 1, 0, and 4 m; (7–8 September; >22 h) 2 m; (12 September–1 October; >19 days) position determined 18 times, one 2 m move; (10–18 October; > 7 days) 1 and 4 m; (22 and 23 October; >22 h), 2 m; (26–28 October; >45 h) 0 and 0 m; (1 November–1 December; >30<36 days), 12 observations, with four movements of, 1, 1, 1, and 2 m; (8 December–18 January; >41 days) five observations with one movement of 4 m.

Many of the sites were steep rocky slopes with angular rock rubble and talus, all well or partially vegetated. Seventeen sites were recorded as having talus rock and three as having boulder complexes. One site (12 Sepetember–1 October; >19 d) was reoccupied (8 December–18 January; >41 d). Therefore, the snake spent at least 41%, >60 of 147 d, of its time, in two seasonally-distinct occupancies of this site. Two other sites were occupied for periods longer than 48 h, (10–18 October, >7 d 20 h<10 d) and (1 November–1 December; >30 d<36 d).

When the snake was located twice in a day, movements to new sites occurred twice during daylight hours, between 0835–1740 h and 1335–1635 h. In both cases visual contact had been made at the earlier time, potentially influencing the snake's behavior. Times and air temperatures of observed surface activity of Snake #2 at other sites were as follows: 1425 h, 26°C; 1115 h, 24°C; 1515 h, 28°C; 1700 h, 25°C; 1715 h, 25°C; 1450 h, no AT; 0835 h, 14°C; 1335 h, 26°C; 1520–1715 h, 18–15°C. Eleven encounters involved diurnal surface activity.

Snake #2 moved location twice following rains on 28 and 29 August, but failed to move during a daily rainy period 14–18 September, following a heavy rain on 22 September, and after a lighter rain on 23 September. Light rains on 16 October and 24 December failed to result in immediate site relocation.

Following release on 25 August, Snake #2 remained on lower terrace slopes before proceeding southward on 29 August up a steep north-facing slope which it continued to climb until 4 September when it reversed general direction to move northward across Cave Creek where it climbed the south-facing slope and occupied its first long-term site on 12 September. It then returned to lower slopes and crossed to the south side of the Creek where it was at another long-term site by 10 October. On 21 October it was at the Creek and subsequently again moved up the south-facing slopes before settling on 1 November. It remained at this site until at least 1 December, when it relocated 57 m to reoccupy an earlier site (12 September–1 October) where it remained until lost in late January, 30–31. The final two sites were on steep south-facing slopes.

During 147 days, Snake #2 made a mean daily distance relocation of 13.5 m/d. The thirty movements between sites involved a total distance of 1987 m, for an approximate mean distance of 66 m/move (range = 4–175 m). Between release on 25 August and 12 September the distance covered was 1267 m in 19 d, 66.7 m/d, 64% of the total distance moved. Then the snake was resident for >19 days before resuming frequent movements between 4 October and 1 November. These renewed movements (15) of 663 m over 29 days resulted in a mean daily movement of 22 m/d, or 44.2 m/move. After 1 November the snake moved once, 57 m, through 18 January; daily movement during this period was 0.7 m/d.

Discussion.—Above ground observations suggest that Green Ratsnakes do not spend significant amounts of time in the canopies of trees. While actively moving on the ground surface they only seek low objects to increase their elevation. This non-arboreal behavior is in agreement with Schulz (1996). Use of low vegetative perches might be facilitated by the snake's greenish coloration, acting as camouflage. Based on snake body exposures to sunlight, snakes appear to be using these perches as basking sites. Green Ratsnakes and Sonoran Whipsnakes (*Masticophis bilineatus*) are syntopic in Cave Creek, though the extent of overlap in their diets and use of arboreal habitats remains unclear.

Both ratsnakes were observed to exhibit similarly unusual forward-retreat locomotion. Comparable movement has been noted in the Australian Thorny Devil, *Moloch horridus* (Sherbrooke 1999, 2005) and in at least two snakes, the Neotropical Vine Snake (*Oxybelis aeneus*; Fleishman 1985) and the Ridge-nosed Rattlesnake (*Crotalus willardi*, H. W. Greene and D. L. Hardy, Sr., pers. comm.). This slow, forward-retreat behavior for locomotion could be associated with the collection of visual and/or chemical cues used in orientation during surface movements. Or, it could be a method for reducing the likelihood of detection by potential predators, reducing the reactions of motion sensors in the predator's retinal/brain complex, thus inhibiting the processing and identification of visual images.

Both snakes remained at some locations for periods greater than a week. Given the large size of boulders under which these snakes spend a great portion of their lives, it seems that collectors seek-

ing Green Ratsnakes should avoid turning rocks or small boulders, and should consider snakes inaccessible when not exposed. Similarly, these microhabitats probably afford the snakes protection from predators. The evidence of rodent occupation or use at two of three long-term sites used by Snake #1 suggests that such sites might be associated with prey capture and/or digestion; within site movements may facilitate thermoregulation for digestion. Green Ratsnakes readily eat rodents in captivity (Schultz 1996), and rodents are part of the natural diet (Stebbins 2003). Alternatively, Snake #2's use of its last two long-term sites, after 1 November, might be better interpreted as being associated with seasonal inactivity.

Of the 26 diurnal movements of the two snakes, 18 were afternoon, four were morning, and four were undetermined. It appears that surface activity might be most frequent after noon, and probably extends into evening. Schulz (1996) suggested afternoon and evening activity for this subspecies, and a 25°C preferred body temperature for the species (within the range here recorded in Cave Creek). For both snakes, surface activities and movements between sites were not clearly linked to rainfall events.

Snake #1 appears to have been actively foraging with three interrupted periods of site residency before making a long distance move to sites with south-facing exposures, on deep talus slopes. It seems possible that movements during the summer were largely motivated by food acquisition, whereas later in the season the snake was moving to an area for potential hibernation. There are several possible explanations for the disappearance of the snake's signal after 3 October: predation, transmitter failure, movement out of range, or the snake may have moved into a talus slope, or surrounding rocky areas, preventing effective signal transmission. Snake #2 appears to have also been actively foraging with two interrupted periods of longer site residency. Beginning 1 November it may have entered a pseudo-hibernation stage, from which it emerged in early December to move to another south-facing slope where it remained, although active under the surface, through at least 18 January. Subsequently the signal and snake were lost, but excavation of the final undisturbed site (31 January 2000) did not lead to recovery of the transmitter or snake, suggesting that the snake had moved. Transmitter batteries might have failed. Movements during December and January by Snake #2 suggest that a single hibernation site may not be selected, but rather that snakes might continue to relocate during winter.

Acknowledgments.—I thank SWRS Volunteers and others at the Southwestern Research Station who assisted, especially C. J. Cole, K. Hurley, V. Prichard, H. Serraino, and B. Tomberlin. A. Ortiz captured the 1994 snake. D.L. Hardy, Sr., provided and implanted the radiotransmitters. C. J. Cole and C. R. Townsend located references. Arizona Game and Fish Department and the Douglas Ranger District, Coronado National Forest, provided permits.

Determining status and trends of crocodilian populations is a top priority of crocodile conservation and management programs (Bayliss 1987; Thorbjarnarson 1992). A variety of crocodilian survey methods have been developed (Bayliss 1987; Magnusson 1982). Spotlight surveys have been used successfully and have proven effective throughout the world to evaluate crocodilian populations (Bayliss 1987; Chabreck 1966; Hutton and Woolhouse 1989; King et al. 1990; Magnusson 1982; Mazzotti 1983; 1999; Thorbjarnarson 1988; Webb et al. 1987; Woodward and Moore 1993). Spotlight surveys (also termed night counts or eyeshine surveys) are environmentally versatile, relatively inexpensive, and take advantage of nocturnal crocodilian behavior patterns and enhanced visibility due to eyeshine (light reflected from the *tapetum lucidum*) (O'Brien 1990). Surveys are usually conducted with a spotlight from a boat, but can also be done from other vehicles or on foot. Spotlight surveys report an encounter rate of crocodiles, usually as animals per distance of shoreline or river, as an index of relative density (Wood et al. 1985).

Selection of specific survey methods depends greatly upon biology of the species under study and other considerations such as habitat, cost, logistical constraints, and goals of the study (Chabreck 1966; Magnusson 1982). Regardless of method used, factors that

influence interpretation of survey results need to be considered, and controlled or estimated if possible (Bayliss 1987; Graham and Bell 1969). The proportion of animals visible (sightability or detectability) during surveys is an important variable (Gardner and Baard 1999; Nichols et al. 2000; Woodward et al. 1996). The probability of observing a crocodile is dependant upon several factors. Environmental variables such as water temperature, water depth, wave action, and tidal fluctuations can affect the number of crocodilians observed during a spotlight survey (Bayliss 1987; Montague 1983; Murphy 1977; Woodward and Marion 1978). Habitat conditions, such as shape and complexity of the shoreline, width of river or pond, and presence and density of vegetation also affect visibility of crocodiles (Thorbjarnarson 1988; Wood et al. 1985). Furthermore, visibility of crocodilians may be affected by survey craft size and speed, light source (power, color, and location with respect to the observer), and observer skill (Bayliss 1987; Woodward et al. 1996). Finally, wariness of individuals to the observer (e.g. escape distance) and population density can affect results of spotlight surveys (Pacheco 1996; Webb and Messel 1979). In this study we examined the effect of shoreline vegetation on visibility of crocodiles during spotlight surveys.

Materials and Methods.—Two experiments were designed to imitate a crocodilian spotlight survey. Surveys were conducted along Red Mangrove (*Rhizophora mangle*) shorelines within habitat of the American Crocodile (Mazzotti 1999), Long Sound, Monroe County, Florida, USA. Artificial reflectors were used to mimic the presence of crocodiles floating at the surface. One piece of 13 × 13 mm red reflective tape was attached to 1-inch diameter polyvinychloride (PVC) pipes, which were painted black (termed reflectors).

Reflectors were positioned at randomly selected points along transects by individuals who did not participate in the surveys. Total number of reflectors was calculated with a power analysis using a 95% confidence interval and a probability that 80% of reflectors visible during the survey would be observed. Half of the reflectors (exposed) were placed along the shoreline, at the mangroves' edge. PVC pipes used in this treatment group were approximately 75 cm in length and were inserted into the mud substrate, leaving the reflective tape just above the waterline. The remaining reflectors (concealed), 10 cm in length, were placed among mangrove roots approximately 1.75 m inland from the vegetation edge along the shoreline. In both concealed and exposed groups, reflectors were placed so that they would be available for spotlighting during a survey. The location of each reflector was recorded using a global positioning system (GPS) receiver.

In Experiment 1, 121 reflectors (59 concealed and 62 exposed) were placed along the same 6 km stretch of shoreline at randomly selected points. A boat driver and an observer conducted the survey from a 4.6 m skiff. The skiff traveled parallel to the shoreline, approximately 50 m offshore, at a speed ranging from 24–27 km/h. A 200,000-candle power spotlight was used in a back and forth sweeping motion on the side of the boat facing the shoreline. When a reflector was observed the boat slowed to approach the shoreline and identify each reflector as either concealed or exposed.

In Experiment 2, 110 reflectors, evenly divided between exposed and concealed, were placed along two separate 6.4 km shorelines (half as dense as Experiment 1). The survey was performed in the same manner as in Experiment 1, except only a waypoint was recorded with the GPS unit, rather than slowing to approach the reflector. Since exposed and concealed treatments were located on separate shorelines we knew reflector locations for each and only needed to record a GPS coordinate. Waypoints were also taken to ensure that only reflectors were counted rather than incidental reflective objects (false positives or actual crocodiles). The location of reflectors recorded by each observer during a single run along the shoreline was verified by overlaying each observer's waypoints with the known positions of all reflectors, using a geographic information system. A Two-Sample t-Test was performed to analyze differences between numbers of reflectors observed.

We hypothesized the effect of shoreline vegetation depth on visibility of crocodiles by drawing a sigmoid curve through the mean proportion of reflectors counted by observers in Experiment 2. We assumed that the sighting proportion would continue to decline at a similar rate until it approached zero. Under this hypothesis, few animals would be sighted further than 5 m from shoreline.

Results.—Four observers who participated in Experiment 1 located all 62 (100%) exposed reflectors, with two observing 54 (92%) and two observing 57 (97%) concealed reflectors (Table 1). A significant difference was found between the number of reflectors observed that were concealed and those that were exposed ($p = 0.0003$). Approximately 26% fewer reflectors (Table 1, $p = 0.0014$) were observed in concealed positions (range 24–65%) than exposed positions (range 69–91%). Figure 1 is a hypothetical curve of loss of visibility of crocodiles inland from the edge of shoreline vegetation.

Discussion.—Shoreline vegetation decreased visibility of reflectors during surveys. With one exception the proportion of reflectors sighted was consistent within treatments. In the exception (24%

TABLE 1. Number (percentage) of reflectors (experimental eyeshines) spotted by each observer. N equals the number of reflectors available. Exposed reflectors were placed along a mangrove shoreline and concealed reflectors were placed 1.75 m into mangrove vegetation. The difference between exposed and concealed reflectors observed was significantly different for both experiments ($p < 0.01$, Two-Sample t-Test).

	Experiment 1			Experiment 2	
	Exposed	Concealed		Exposed	Concealed
Observer	N = 62	N = 59	Observer	N = 55	N = 55
1	62(100)	57(97)	1	45(82)	13(24)

concealed observed in Experiment 2) the observer missed several reflectors at the beginning of the survey bringing down the overall score. Although many studies acknowledge that decreased sightability of crocodiles can occur in vegetated areas (Bayliss 1987; Da Silveira et al. 1997; Magnusson 1982; Woodward et al. 1996), even possibly to the point of rendering spotlight surveys ineffective (Graham and Bell 1969), few have quantified effects of vegetation. In addition, the further the crocodilian is within vegetation, the less visible it is (Fig. 1). However, even 5 m inland of the mangroves' edge allows for eyeshine detectability. Thorbjarnarson (1988) found that in Haiti, shoreline vegetation prevented 50% of the crocodiles present from being observed.

While the results may be intuitive (animals whose eyeshine is unobstructed to the observer are more likely to be seen), accounting for effect of decreased detection probability is essential for developing robust and reliable indices of relative population density (Bayliss 1987; Gardner and Baard 1999). It may not always be possible to get an accurate assessment of detectability (Graham and Bell 1969), but as long as bias is consistent, the index of relative density is stable relative to the true count (Da Silveira et al. 1997). When bias cannot be accurately estimated it should be minimized through standardized survey design (Graham and Bell 1969; Magnusson 1982; Wood et al. 1985; Woodward and Marion 1978).

In addition to vegetation, density of animals and speed of survey may have affected detectability. In Experiment 1, we found that survey speed affected the number of crocodiles observed. As a reflector was approached to determine its placement, additional reflectors were sighted that might have otherwise gone unnoticed had the boat not slowed to approach the shoreline. Hutton and Woolhouse (1989) reported that observer error was much lower when the survey was performed at slower speeds. Importantly, this suggests that especially at low densities the more crocodiles there are, the more likely they are to be observed and that although detectability may be consistent among observers it is not constant relative to other conditions. Therefore, in habitats where crocodiles are rare and/or vegetation is dense, animal counts might be more accurate at slower boat speeds, if not occasional pauses. Certainly, approaching individuals to identify species and make size estimates increases the likelihood of sighting nearby animals.

There was relatively little variation in vegetation within shoreline areas chosen for these experiments when compared to variation in vegetation throughout crocodile habitat in northeastern Florida Bay, Everglades National Park (Mazzotti 1983, 1999). In some areas the edge of shoreline vegetation extended inland 10–15 m and seaward 25–30 m. Density of shoreline vegetation ranged from absent (0% cover) to impenetrable (100% cover). We assume that sightability of crocodiles varies with width and density of vegetation as expressed in Fig. 1. Under these conditions a correction factor for the presence of vegetation is not appropriate. A better strategy here is to minimize the effect of vegetation. To minimize impact of vegetation on visibility of crocodiles in Florida, we recommend that surveys for relative density of crocodiles be conducted during low water levels of the spring dry season.

Bayliss (1972) put goals of crocodile management into three main categories: conservation of rare species, harvesting for sustained yield, and control of unacceptable crocodiles. In South Florida a new category of "indicator of ecosystem integrity" is emerging as the most important objective of crocodilian studies (RECOVER 2004; Rice et al. 2005). All of these goals require monitoring of long-term trends in population size. Due to constraints of time and money, monitoring of crocodilians will depend on using indices of population parameters such as density and abundance. This underscores the importance of increasing confidence in estimates of relative population density by estimating or controlling potential sources of bias during surveys.

Acknowledgments.—We thank researchers and field technicians who assisted with the surveys; they include Laura Brandt, Mathew Chopp, Geoff Cook, Amber Dove, Victoria Foster, Phil George, Kim Rohrs, Tina Ugarte, Hardin Waddle, and Joe Wasilewski. We thank Nicole Gibson for her advice on statistical analyses. We also thank J. Perran Ross, John Thorbjarnarson, and Allan Woodward for commenting on the manuscript and Holly Fling for editorial assistance. This project was supported by the U. S. Department of Interior, Critical Ecosystems Studies Initiative, the U. S. Geological Survey, Florida Integrated Science Center, and the University of Florida. Several parthenogenetic species of *Aspidoscelis* have clonal divergence characterized by distinctive color patterns, with one example being *A. tesselata* (Taylor et al. 1996, 2003; Walker et al. 1997; Zweifel 1965). *Aspidoscelis tesselata* is a diploid parthenogenetic species originating from a recent (Densmore et al. 1989; Reeder et al. 2002) single hybridization event (Cordes and Walker 2003; Maslin 1967) between *A. marmorata* and *A. gularis septemvittata* (Dessauer and Cole 1989; Dessauer et al. 1996; Neaves 1969; Parker and Selander 1976). A second example is *A. neotesselata* (Walker et al. 1997), a triploid parthenogenetic species (Wright and Lowe 1967) originating from an *A. tesselata* x *A. sexlineata* hybridization event (Dessauer and Cole 1989; Neaves 1969; Neaves and Gerald 1969; Parker and Selander 1976). The three pattern classes presently identified in *A. neotesselata* (A, B, and C) are described and illustrated by Walker et al. (1997). Although the geographic ranges of *Aspidoscelis neotesselata* and *A. tesselata* are largely allopatric, these species share similar distributional characteristics—small, disjunct groups, with an element of unpredictability in their locations within expanses of apparently similar or suitable habitats (Hammerson 1999; Walker et al. 1997; Zweifel 1965).

An unreported population of *Aspidoscelis neotesselata* of Pattern Class B was discovered in 1999 by RJR and JS during ecological studies at the Pueblo Chemical Depot (PCD), Pueblo County, Colorado. The purpose of the present study was to document the presence of *A. neotesselata* at PCD, describe its unusual color pattern variation, illustrate the ontogenetic convergence of a color pattern variant on Pattern Class B, and place the PCD population in the geographical context of other populations of *A. neotesselata* in its vicinity.

Typical habitats utilized by *A. neotesselata* at PCD were associated with Chico Creek (a shallow, ephemeral tributary of the nearby Arkansas River), particularly the west bank and "islands" of low relief in its dry, braided channel. Collecting sites were characterized by a sandy substrate with one or more of the following features: open stands of Sand Sagebrush (*Artemisia longifolia*), Rabbitbrush (*Chrysothamnus nauseosus*), Siberian Elm (*Elmus pumila*), and Tamarisk (*Tamarix ramosissima*), or dead, prostrate cottonwood (*Populus deltoidea*) trunks, limbs, and other flood

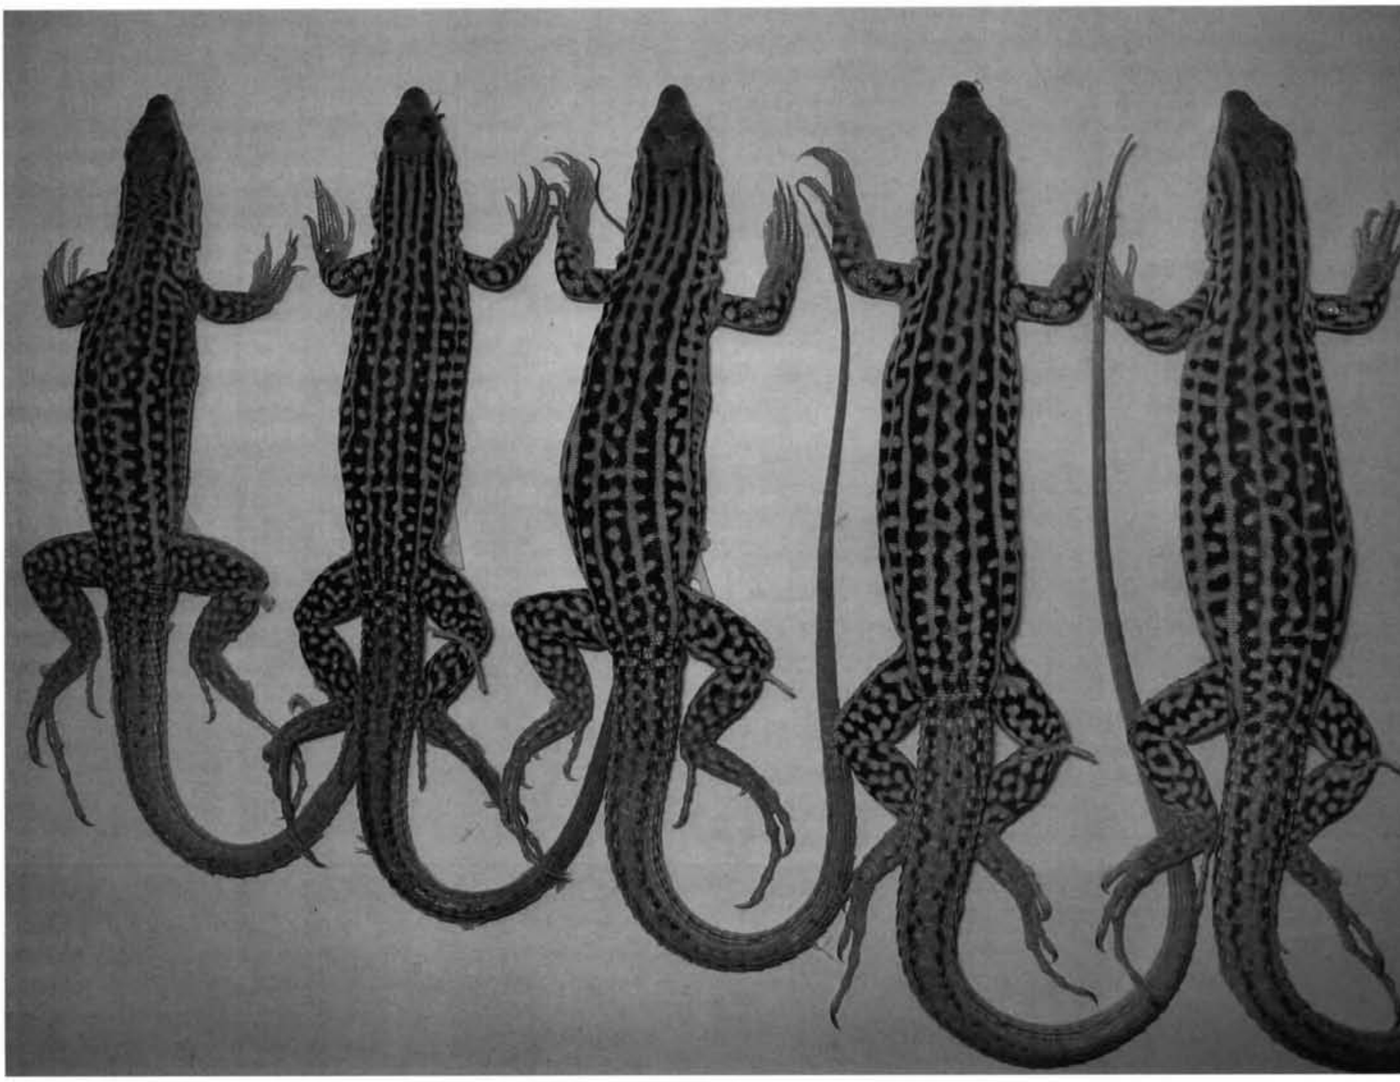

FIG. 1. Color pattern variation among representatives of *Aspidoscelis neotesselata* from Pueblo Chemical Depot, Pueblo County, Colorado. Left to right: Novel color pattern: HLT 2 (78 mm SVL); examples of Pattern Class B (PCD-B), left to right: HLT 5 (81 mm SVL), HLT 20 (88 mm SVL), HLT 34 (97 mm SVL), HLT 33 (101 mm SVL).

debris. These sites were also used by *A. sexlineata*, the paternal progenitor of *A. neotesselata*.

The PCD sample (Appendix I) can be divided into three groups based on color pattern differences. The first group, PCD-B (Fig. 1), was represented by 14 of 26 individuals fitting the description of Pattern Class B of *A. neotesselata* (Walker et al. 1997). These individuals had the vertebral (middorsal) dark field occupied by either a single zigzagged line or by a line anteriorly and a linear series of spots posteriorly. Vertebral line and spots were white, gray, or tan and of similar intensity and hue.

The second group, PCD-B2 (Fig. 2), comprised 11 of 26 individuals. Juveniles had an essentially continuous, tightly undulant vertebral line with a subdued tan central region and contrasting white or gray lateral elements or spots associated with the apices of the zigzags. For comparison, a representative of Pattern Class B, similar in size to HLT 38 (Fig. 2), is illustrated by Walker et al. (1994, their Fig. 2). In PCD-B2, the initial high contrast between vertebral line and lateral elements diminishes with growth until the principal difference between large individuals of PCD-B and PCD-B2 is a thicker vertebral line in the latter (Figs. 1 and 2).

Total variance explained	32.1%	27.0%

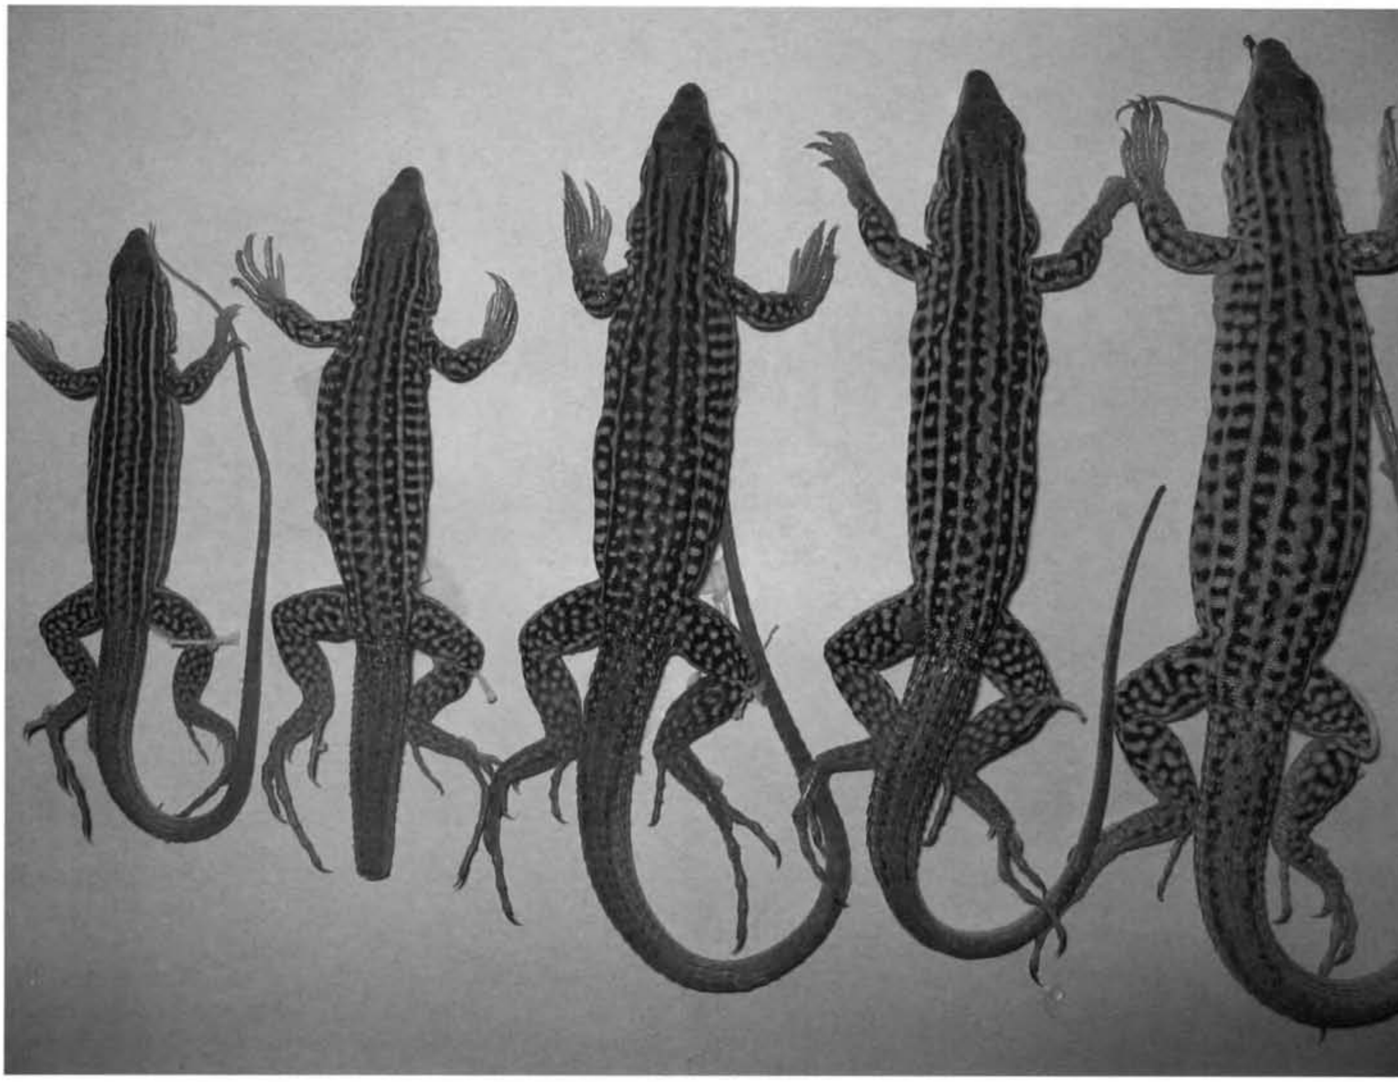

FIG. 2. Color pattern variation among representatives of *Aspidoscelis neotesselata* from Pueblo Chemical Depot, Pueblo County, Colorado. Examples of the Pattern Class B variant (PCD-B2), left to right: HLT 38 (57 mm SVL), HLT 6 (68 mm SVL), HLT 1 (80 mm SVL), HLT 13 (84 mm SVL), HLT 107 (97 mm SVL). Note the wider vertebral line in this variant of Pattern Class B.

The third group consisted of a single individual with a novel color pattern (HLT 2) collected approximately 635 m east of the nearest Chico Creek collecting site (Appendix I). Aberrant color pattern elements included medially displaced, disrupted paravertebral stripes on the neck, transverse tan bars compromising the integrity of the paravertebral stripes posteriorly, and the absence of a vertebral line at midbody (Fig. 1).

Although *A. neotesselata* at PCD was assignable to Pattern Class B based on the final color pattern attained, PCD-B and PCD-B2 differed in their color pattern transition from juveniles to large adults. Unlike isolated cases of novel color patterns that occasionally appear within a known pattern class (e.g., HLT 2, Fig. 1; Walker and Cordes 2003), the pattern class denoted as PCD-B2 was represented by individuals of different size (age) classes—thus by different cohorts. The most parsimonious hypothesis is that genetically based color pattern alternatives are being inherited in a clonal pattern at PCD. The alternative hypothesis would require the action of some unknown epigenetic factor or factors to produce PCD-B2 individuals on an annual basis. Representatives of both PCD-B and PCD-B2 were found at all Chico Creek collecting sites. One feature of Pattern Class B (the extension of dorsal dark fields onto the tail, Walker et al. 1997) was highly variable in the PCD population, ranging from essentially absent to prominent (Figs. 1 and 2).

We summarized the pattern of morphological variation in the PCD population of *A. neotesselata* by principal components analysis (PCA), with the PCA model (Table 1) based on a correlation matrix of 10 meristic characters (Appendix II). With two notable exceptions, the PCD sample appeared to represent a single morphological entity as depicted by an ordination of principal component scores. Scores for two specimens fell outside the 95% confidence ellipse of sample variation (Fig. 3). One outlier (Fig. 2, HLT 1) was an individual expressing an extraordinary number of breaks (by dark bars) in the lateral stripe (29 total), dorsolateral stripe (8 total), and paravertebral stripe (18 total). The second outlier (HLT 2, Fig. 1) was characterized by low counts for GAB (77), FP (34), COS (9), and PV (6), all well below the lowest values for the balance of the sample. Because PCD *A. sexlineata* (N = 12) had

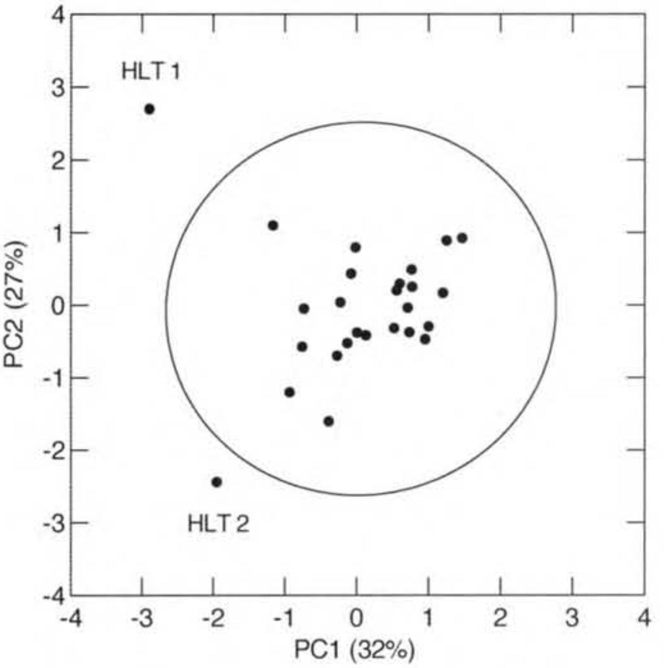

FIG. 3. Pattern of morphological variation in *Aspidoscelis neotesselata* from Pueblo Chemical Depot, Pueblo County, Colorado. Ordination of principal component scores for 26 specimens on the first two principal components (Table 1). The ellipse defines 95% of the sample variation (the two outliers are described in the text).

low counts for these characters (GAB, 75.7; FP, 32.5; COS, 6.2; PV, 10.1), we considered the possibility that this individual was a tetraploid hybrid between *A. neotesselata* and *A. sexlineata*. This hypothesis was rejected based on the apparent fertility of HLT 2, an individual with a developing clutch of three vitellogenic ovarian follicles of 6, 6.1, and 5.7 mm diameter and oviducts that were expanded and fully functional.

Because Pattern Class B is the only pattern class of *A. neotesselata* in syntopic contact with both parental species (local contact in the vicinity of Higbee, Colorado; Walker et al. 1990, 1995), we hypothesize, presuming a single hybridization event in the origin of *A. neotesselata* (Walker et al. 1997), that Pattern Class B represents the ancestral color pattern. This would imply that Pattern Class B2 originated by mutation in Pattern Class B at PCD. Other populations of *A. neotesselata* in the PCD vicinity (Walker et al. 1997), and their linear distances from the PCD population are Pattern Class B (27 km south at Huerfano Canyon), Pattern Class A, (27 km west at Pueblo Nature Center), and Pattern Class C (27 km southwest at the historic townsite of Lime). All color pattern classes described for *A. neotesselata* are in closest proximity in this small area. These populations will be particularly important in resolving patterns of evolutionary divergence in *A. neotesselata*.

Acknowledgments.—We are grateful to the U.S. Army, Pueblo Chemical Depot, for permission to conduct this study at PCD and K. M. Canestorp, U.S. Fish and Wildlife Service, for coordinating access to the site. The study was made possible by Scientific Collecting Licenses 03-HP772 and 04-HP772A1 issued to HLT by Colorado Division of Wildlife and by TSSC and SPARC summer research grants awarded to HLT by Regis University. We thank C. J. Cole, T. W. Reeder, and R. E. Espinoza for comments and suggestions that improved the manuscript.

APPENDIX I
Specimens Examined

Aspidoscelis neotesselata: Pueblo Chemical Depot, Pueblo County, Colorado, USA. Along south boundary fence, east of Chico Creek, HLT 2 (UTM 13S 555537, 4236036); west side Chico Creek (1): HLT 4–6, 11–13, 22, 107, 136 (UTM 13S 554843, 4236110); (2) HLT 1, 3, 14, 21 (UTM 13S 554856, 4236332); (3) HLT 18–20, 33–38, 133–135 (UTM 13S 554734, 4237814).

APPENDIX II
Meristic Characters

GAB = number of granular dorsal scales in a single row around midbody (the 15th ventral scale posterior to the axilla established the point for beginning this count); COS = bilateral total of circumorbital scales; LSG = sum of lateral supraocular granules on both sides of the head (the count includes all scales between the supraoculars and superciliary scales, anterior to the suture line between the third and fourth supraoculars); FP = sum of femoral pores on both thighs; L-breaks = total number of interruptions by black pigment of the lateral stripes; DL-breaks = total number of interruptions by black pigment of the dorsolateral stripes; PV-breaks = the total number of interruptions by black pigment of the paravertebral stripes; PV = number of scales between paravertebral stripes at midbody; SDL-T4 = number of subdigital lamellae on the fourth toe of one foot (right was chosen unless damaged); ILS = all interlabial scales between the lower labials and sublabials counted anterior to the suture line between 5^{th} and 6^{th} lower labials; SVL = length of body from tip of snout to posterior edge of preanal scales (in mm).

Herpetological Review, 2006, 37(1), 44–45.

Diet of *Pipa carvalhoi* (Amphibia, Pipidae) is Not Influenced by Female Parental Care

CLARISSA CANEDO[1]
JOÃO P. GARCIA
RONALDO FERNANDES
and
JOSÉ P. POMBAL JR.
Departamento de Vertebrados, Museu Nacional/UFRJ
Quinta da Boa Vista, 20940-040 Rio de Janeiro, RJ, Brazil

[1]*Corresponding author; e-mail: canedo@mn.ufrj.br*

Costs of parental care may include increased risk of predation, reduced mating opportunities, and reduced food intake (Crump 1995). The latter cost is particularly important to females as they have a large gametal investment compared to males. Consequently, reduced food intake may limit future clutches, reduce the number of eggs per clutch, and retard growth rate which, indirectly, also may decrease fecundity as it is correlated with female size (Salthe and Duellman 1973).

The benefits of parental care to reproductive success have been documented for certain species, but the costs have been rarely quantified (Crump 1995). Simon (1983) reported reduced feeding in *Cophixalus parkeri* (Microhylidae) and Townsend (1986) found similar results for *Eleutherodactylus coqui* (Leptodactylidae). Parental care in these species requires that the parent remain near the clutch; this behavior may negatively affect foraging activity (Crump 1995).

Crump (1995) suggested that the cost of parental care is reduced in species that transport eggs because carrying eggs adhered to the body does not preclude foraging activity and causes no reduction in the feeding efficiency. Transport of eggs is known in four anuran families: Discoglossidae, Hylidae, Pipidae, and Myobatrachidae (Duellman and Trueb 1986). Female *Pipa* carry eggs in the dorsal skin, where either tadpoles or juveniles emerge, according to the species (Trueb and Cannatella 1986).

Data concerning the diet of *Pipa carvalhoi* (Miranda Ribeiro, 1937) are scarce and anecdotal. The species is aquatic but Myers and Carvalho (1945) observed some individuals leaving a lake during and after a rain, apparently foraging for insects. Weygoldt (1976) described the feeding behavior of *Pipa carvalhoi*, and also reported some types of prey. Nevertheless, his study was performed in the laboratory and, therefore, the number of available kinds of prey was limited. There are no studies analyzing food items in the diet of this species under natural conditions.

We studied the diet of *Pipa carvalhoi* in seminatural conditions and compared the diet of females carrying developing eggs on their backs to the diet of males and females without eggs, in order to analyze the influence of this kind of parental care on feeding.

Materials and Methods.—Specimens were collected by U. Caramaschi on 11 March 1986 at the campus of Comissão Executiva do Plano da Lavoura Cacaueira -CEPLAC, Municipality of Ilhéus, State of Bahia, Northeastern Brazil. Specimens were collected in a fishfarm pool with no fish at the time of collecting (U. Caramaschi, pers. comm.). All specimens are deposited in the herpetological collection of Museu Nacional, Rio de Janeiro, Brazil (MNRJ 19527, 19529–30, 19533, 19535–36, 19538, 19540–19550, 19554–19559, 19566, 19573, 19589–90, 19596–97, 19605, 19608, 19610, 19612, 19620, 19633, 19645, 19676, 19685, 19698, 19701, 19704, 19707–19709, 19711, 19714, 19717, 19719, 19728, 19741, 19749, 19760, and 19766). In 2003, 54 specimens were analyzed and grouped into three classes: six females transporting eggs, 20 females without eggs, and 28 males. The snout–vent length (SVL) and the mouth width (MW) of each specimen were measured with calipers (nearest 0.05 mm). The stomachs were removed and food items were identified and counted under a stereomicroscope. Stomach contents were dried in an oven and weighed on an electronic balance (nearest 0.001 g).

Numeric frequency ($\%n_i = n_i / \sum n_{1\text{-}n}$ where n_i is the number of prey of category i) and occurrence frequency ($\%oc_i = oc_i / N$, where oc_i is the number of stomachs with category i and N is the total number of analyzed stomachs) were calculated based on the prey categories found in the stomach contents of each class. Statistical analyses were performed after testing for assumptions (homocedasticity, normality, and parallelism); when appropriate, non-parametric techniques were employed. Analyses of covariance (ANCOVA) were conducted to compare the mass of stomach contents among classes, using SVL as the covariant variable to remove the effect of size difference among classes. The non-parametric Kruskall-Wallis test was performed to compare the

TABLE 1. Total number of prey (N), numeric frequency (%n), and occurrence frequency (%oc) of prey categories in the diet of each class of *Pipa carvalhoi*. NI indicates unidentified items. M (Q_1;Q_3) show the median, first and third quartiles in the distribution of the number of prey per specimen.

number of prey in the stomach contents and the number of categories ingested by different classes. Similarity among diets of the different classes was calculated by Pianka's Overlap Index (Krebs 1989).

Results.—Aquatic arthropods were the most frequent prey items we found in *Pipa carvalhoi* stomachs (Table 1). Chironomid larvae represented most of the prey (> 98%) and were found in nearly all specimens of the three classes (%oc varied from 70 to 100%). Fragmented material and grains of sand were also a dominant component of the stomach contents (%oc 50% or higher).

There was no difference in mass of stomach contents among the three classes ($F_{2,44} = 0.94$; $p = 0.40$). There were also no differences among classes in number of prey per stomach (H [2, N = 44] = 0.68, p = 0.71) or the number of prey categories per stomach (H [2, N = 54] = 5.23, p = 0.07). The diet of the three classes was qualitatively similar (Overlap Index approximately 0.9999 considering all possible combinations), probably due to the high numeric frequencies of chironomid larvae in all classes.

Discussion.—Our results show that female *Pipa carvalhoi* carrying eggs at this site had no difference in food ingestion compared to males or females without eggs. It suggests that carrying eggs in *Pipa carvalhoi* is a kind of parental care that does not affect diet, at least in the studied population, probably because it does not interfere with the mobility of parents, supporting the hypothesis suggested by Crump (1995).

All three classes appeared to feed mainly in water. If these frogs leave the water to forage, as suggested by Myers and Carvalho (1945), this habit was not frequent in the studied population.

According to Weygoldt (1976), *Pipa carvalhoi* captures chironomid larvae together with sediment and sand, sucking the larvae into the mouth. This author observed that although the frog discards some of the sand before ingesting the larvae, much of the sand and sediment is ingested with the prey. This behavior might explain the high frequency of fragmented material and grains of sand found in the stomach contents of the three analyzed classes.

Acknowledgments.—Thanks are extended to Martha Crump and Daniel S. Fernandes for their helpful suggestions on the manuscript; to Márcia S. Couri and Carlos Frederico D. Rocha for loaning equipment; to Conselho Nacional de Desenvolvimento Científico e Tecnológico – CNPq, Fundação Carlos Chagas Filho de Apoio à Pesquisa do Estado do Rio de Janeiro – FAPERJ, and Fundação de Apoio à Pesquisa do Estado de São Paulo – FAPESP for financial support and to Programa de Iniciação Científica Júnior – PICJr. C. Canedo acknowledges the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Capes for the fellowship.

Observations of Courtship, Copulation, and Gestation in the Wet Tropical Endemic Skink *Carlia rubrigularis*

AMANDA M. LANE
School of Biological Sciences, University of Sydney, Australia, 2006
e-mail: alane@bio.usyd.edu.au

Carlia rubrigularis (Ingram and Covacevich 1989) is a small (maximum 55 mm SVL; Cogger 2000), ground dwelling, heliothermic skink, endemic to the Wet Tropics region of north Queensland, Australia. Adults are sexually dimorphic, with females averaging heavier (3.1 g) and longer (50 mm SVL) than males (2.6 g, 46 mm SVL). Though morphologically conservative in scalation and other taxonomically important characters, members of the genus *Carlia* are highly variable in color (Cogger 2000). Presence of a distinctive red flush on the throat that extends around the neck and forearms in breeding males distinguishes *Carlia rubrigularis* from other members of its genus.

Carlia rubrigularis is an oviparous seasonal breeder, mating occurring at the onset of the wet season in September (Wilhoft 1963a). Like all congeners for which it is known, *C. rubrigularis* lays two eggs per clutch (Cogger 2000; Greer 1990); and multiple clutching is likely (Wilhoft 1963a; 1963b). Only one brief observation of courtship exists, where a male was seen to grasp a female in his jaws just behind her right forelimb and attempt copulation, but the female broke free and fled (Wilhoft 1963a). Scant data on reproductive behavior in *C. rubrigularis* led me to summarize observations I made in the field and during the course of mate choice trials.

During 30 mate choice trials conducted in the austral spring and summer (September to February) 2000–2001, I observed 19 courtship episodes when an adult female was placed in a 375-liter tank (100 x 75 x 50 cm) with two adult males that were tethered to different sides of the tank, partly divided by an opaque plastic partition. Two additional observations of courtship were made in the field at Gillies Lookout, an open eucalypt woodland in the Wet Tropics District (17°10'13"S, 145°41'15"E; elev. 720 m). Both courting pairs were observed in the undergrowth, near dense grassy tussocks ca. 50 cm high. Only one of these 21 interactions resulted in a successful copulation.

Courtship.—Both sexes initially investigated their conspecific using tongue flicks to the body, as seen in other lizards (Carpenter and Ferguson 1977; Mason 1992) and other species of *Carlia* (Langkilde and Schwarzkopf 2003; Whittier 1993), implying a role for pheremonal cues in sexual identification and stimulation. The courting male then performed a body shudder/spasm, involving jerking, quivering and twitching movements of the whole body. Head bobbing, tail twitching and a steady approach of the female accompanied the body shudder behavior at least 80% of the time. This behavior lasted between 4 sec and 6 min and could occur intermittently over the 30 min interval of the mate choice trial. Non-receptive females either fled, flicked their tails rapidly, or laterally presented to the male by orienting the longitudinal axis broadside while flattening the body dorsoventrally. After several seconds of tail flicking or lateral presentation the male either ceased performing the shudder behavior and approaching or, if he continued his approach, the female moved beyond his tethered reach. Lateral presentation is generally considered to be an aggressive/rejection behavior (Whittier 1993), as is tail flicking (Langkilde and Schwarzkopf 2003). If the female remained in a fixed position, allowing the male's approach, the male attempted to grasp her at the lateral mid-body region in his jaws. At this stage, the one receptive female became limp, whereas all other females bit the male repeatedly until able to escape his grasp.

Observations made in the field were largely consistent with those made in the lab, except that the initial investigative tongue flicks were to the air rather than to the body region and the body shuddering and approach towards the female occurred extremely quickly in the field, with the entire episode lasting less than one minute in both cases. In the field, one female rejected the male by laterally presenting; the second female rejected the male by fleeing.

Copulation.—When the one receptive female became limp within the jaws of the male, he carried her to a corner of the tank and manipulated his cloaca into contact with hers by pushing her sideways while bringing the base of his tail up and under hers. The right hemipene was intromitted and the copulation lasted 6 min and 47 sec. This is similar to the 3–4 min copulatory interval reported in *Carlia jarnoldae* (Langkilde and Schwartzkopf 2003) and the 3–5 minutes reported in *Carlia rostralis* (Whittier 1993). Throughout the copulatory interval, the female remained immobile in the jaws of the male, with the male positioned roughly crossways on top of her and with the end portion of his tail undulating in front of her head. When copulation ceased, the male loosened his grip and the female fled to another part of the tank.

Gestation.—I captured 52 female *C. rubrigularis* between 19 September and 29 October 2000, over 75% of which were gravid, and all of which were housed with female conspecifics. The last clutch of eggs laid by this group of females was on 11 December 2000. Although their mating dates are unknown, this indicates a gestation period of at least 43 days. The aforementioned successful copulation occurred on 23 November 2000 and this female laid two eggs on 3 January 2001. This 41-day gestation is roughly congruent to the 43-day estimate.

Acknowledgments.—Comments from Richard Shine and Marc Hayes greatly improved this manuscript. The research adhered to the Guidelines for the Use of Animals in Research, the legal requirements of Australia, and the guidelines for The University of Queensland. Ethics approval was obtained from The University of Queensland Animal Ethics Committee: Approval number ZOO/ENT/357/00/URG. Scientific Purposes Permit number F1/000357/00/SAA covered the collection of animals.

Amphibian species disappearances, population declines and massive mortalities have been among the most enigmatic global biodiversity problems in recent decades (Blaustein and Kiesecker 2002). The discovery of chytridiomycosis, a cutaneous disease caused by the chytrid fungus *Batrachochytrium dendrobatidis* (Berger et al. 1998; Daszak et al. 2003), has assumed a prominent place in current investigations on the possible causes of many of these events.

Despite its recent discovery, chytridiomycosis now has been reported in 39 countries, on six continents (Woodhams et al. 2003), including Venezuela (Bonaccorso et al. 2003; Hanselmann et al. 2004). One hypothesis that explains the worldwide distribution of this pathogen argues that it has recently originated and dispersed through naive populations by human activities. Alternatively, *B. dendrobatidis* may have been a widespread organism associated with amphibians, but recent global environmental changes altered this pre-existing relationship, favoring the occurrence of epidemics in different parts of the world (Berger et al. 1998; Daszak et al. 1999). The low genetic variability among geographic strains (Morehouse et al. 2003) and the presence of the pathogen in amphibians of the trade market (Hanselmann et al. 2004; Mazzoni et al. 2003) have favored the former hypothesis (Daszak et al. 2001; Weldon et al. 2004). Nonetheless, the presence of *B. dendrobatidis* in many so-called 'pristine' habitats, relatively removed from human impact, continues to be puzzling.

One corollary to the hypothesis of human-mediated translocation of *B. dendrobatidis* is that the pathogen should be absent from areas isolated from human influence. The presence of the pathogen in such areas, therefore, would challenge this hypothesis. This corollary, however, is extremely difficult to refute because the probability of detecting declines in these areas is very low; very few amphibian studies are carried out in remote locations with a history of limited human contact.

Retrospective analysis of herpetological museum notes revealed amphibian mortalities at the Chimantá Massifs and Auyán-tepui in the Venezuelan Guayana region, South America (Ayarzagüena et al. 1992; Gorzula and Señaris 1998). These two reports are similar to many others in three aspects; they occurred at high altitudes (>1800 m), in pristine habitats, in the late 1980's. However, in contrast to other sites where unexplained mortalities were reported, these sites are located in remote areas that have been visited by humans only during a few scientific explorations. Not only are they difficult to reach and unsuitable for human occupation, but Amerindian communities have long believed that these are places forbidden for humans. Chimantá Massif is an assemblage of 10 sandstone table mountains with a summit area of 1470 km^2. The first expedition was recorded in 1946, and seven more were documented between 1946 and 1978 (Huber 1992). In contrast, Auyán-tepui is a large mountain of ca. 700 km^2. Although these are some of the best explored of all table mountains in the Venezuelan Guayana region, these visits have been restricted to few locations mostly in the south-central areas (Huber 1995). Between 1983 and 1986, a group of scientists conducted expeditions to the highlands of these mountains (Huber 1992). Historical records indicate that this particular site was only previously visited in 1946. Many dead adult frogs of *Tepuihyla edelcae*, an endemic species of the summits of these two massifs, were observed at Chimantá, Akopán-tepui (Ayarzagüena et al. 1992) and Auyán-tepui during 1984 (Gorzula and Señaris 1998). Our objective was to determine whether *B. dendrobatidis* could be associated with these mortalities.

Herein, we examined histological samples prepared from 37 specimens of *T. edelcae* deposited at Museo de Historia Natural La Salle (MHNLS), Caracas, collected during expeditions to these localities (Table 1). All animals were alive at the time of collection, except for specimens MHNLS 11002 and MHNLS 11003, both collected on 27 March 1984 at Chimantá XI and XII. Six of the specimens collected alive were found at nearby sites and within two days (25–28 March 1984) of the collection date of the two dead animals. Four toe clips including interdigital membranes and one piece of ventral skin were obtained from each individual. Tissue samples were washed in phosphate buffer, dehydrated through a graded alcohol series, embedded in paraffin wax, sectioned at 5mm and stained with haematoxylin and eosin (Berger et al. 1999). A total of 12 sections, three for each toe clip, were examined on a light microscope for each frog.

No empty or developing zoosporangia of *B. dendrobatidis* or skin lesions were observed in any of the 444 histological sections examined. Some sections of the specimens found dead showed signs of sloughing, but we found no evidence of the pathogen. This pathogen may go undetected in populations with a very low infection rate because histological analyses tend to underestimate the prevalence of *B. dendrobatidis* (Boyle et al. 2004). Although some frog communities that suffered drastic declines showed a low prevalence of infection (15–28%), this was recorded eight years post-decline (Retallick et al. 2004). During disease-induced

population crashes, the prevalence is expected to be much higher. In the Andean region, *B. dendrobatidis* was detected in 67% of *Atelopus* specimens, all caught alive, at the time of population declines (Lampo et al., *in press*). If *B. dendrobatidis* had infected these populations and produced mortalities in many adult frogs, the probability of not detecting infection in 37 specimens would be relatively low. We therefore conclude that the mortality events recorded in 1984 at the Chimantá Massifs and Auyán-tepui were likely not a result of chytridiomycosis. Observations carried out in later expeditions indicated that the mortality events observed during 1984 were not common. What caused these mortalities remains unclear, although global climatic changes seem a reasonable candidate because most of these sites have not been subjected to direct human disturbances. Pounds et al. (1999) hypothesized that warm episodes of El Niño/Southern Oscillations produced a higher elevation cloud base in tropical mountains in Costa Rica during 1983. The possible effects of this phenomenon on the local weather of these summits are unknown. These highlands, characterized mostly by montane shrublands, meadows and open rock communities with forests restricted to large depressions or streamsides, are covered by clouds most of the year. Local climate data are unavailable and weather patterns are totally different from those at adjacent lowlands, with up to 23°C daily variations in temperature. These variations, however, are likely to be amplified during warm years.

The link between chytridiomycosis, human activity and climate change is one fundamental question in amphibian conservation. Although the data presented here cannot be conclusive in demonstrating the absence of *B. dendrobatidis* in frog populations of *T. edelcae*, the accumulation of evidence pointing to the absence of this pathogen from secluded areas is important in evaluating the hypothesis of human mediated dispersal of this pathogen.

Nest site choice in reptiles has received increasing attention in the last 10 years, and several studies have linked maternal choices with nest temperatures (Kolbe and Janzen 2002; Weisrock and Janzen 1999), moisture (Miller et al. 1987; Packard 1991), embryonic survival (Doody et al. 2004; Wilson 1998), offspring sex (Doody et al. 2004; Roosenberg 1996), and other offspring phenotypes (Allsteadt and Lang 1994; Shine and Harlow 1996). The recent finding that reptile mothers may allocate sex (Olsson and Shine 2001) further highlights the importance of future studies of nest site choice in reptiles, and emphasizes the importance of the links among nest site choice, nest temperatures, and the developing embryo.

Quantifying nest site choice in the field, however, has not always been straightforward for several reasons. First, traditionally most studies measure attributes of nest sites that likely explain less variation in nest temperatures than would openness (e.g., aspect, slope, substrate, distance from vegetation). Second, (arguably) the most important structural attribute of nest sites—openness—is often poorly estimated. At worst openness has been estimated by eye, at best with a spherical densiometer, and nest sites are often lumped in into 'shaded' and 'unshaded or exposed' categories, which might obscure important factors influencing nest site choice (Pringle et al. 2003). For example, in species with temperature-dependent sex determination that nest only in open areas, a small difference in canopy openness between two nests, undetected by the method of classifying both as 'unshaded', can be the chief determinant of hatchling sex. Third, despite the importance of openness to nest temperatures, openness should not be used as a surrogate for incident radiation received by the nest site. Depending on the location of canopy gaps relative to the sun's path, there is often substantial variation in incident radiation intensity and hence temperature among sites with the same openness (Pringle et al. 2003), especially at sites with topographic relief (pers. obs.). Finally, incident radiation intensity is often not directly measured at the nest site because of the cost of monitoring a large number of nest sites with solar radiation data loggers.

Herein, we describe the use of hemispherical photography (HP) and gap light analysis (GLA) as an efficient and precise way to quantify nest site choice in reptiles. Specifically, this method quantifies canopy openness and incident radiation intensity for each

TABLE 1. Example output from Gap Light Analyzer. The italicized rows refer to incident (solar) radiation. Low latitude = Cairns; high latitude = Highlands of southern New South Wales, Australia. Dates reflect typical incubation times and periods for the sites. The two key output data rows are emboldened. Trans = transmitted; Extra = extraterrestrial.

nest site (Frazer et al. 1999). In most cases, we believe that these two attributes would be the most influential and therefore most important contributors to nest temperatures, although we acknowledge the potential importance of other attributes (e.g., aspect, Janzen 1994; slope, McCune and Keon 2002). Using these two techniques we determined openness and incident radiation for > 300 nests of the water dragon, *Physignathus leuseurii* and several nests of the southern forest dragon *Hypsilurus spinipes*. These agamid lizards inhabit eastern Australia and excavate a shallow nest typical of many lizards, turtles, the tuatara, and some crocodilians.

The technique involves the use of a camera in the field and a computer analysis of the resultant images. We used a Nikon Coolpix® 995 digital camera with a Nikon FC-E8® fisheye converter lens to take hemispherical photographs. The camera was placed on a level surface at the nest site at ground level, and oriented to magnetic north. This orientation allows the computer program to track the sun's path across the sky (through the canopy) for estimation of incident radiation. Care was taken to make sure the observer was not in the photograph (or at least blocking any sky). This was achieved by taking the photograph while lying on the ground. An alternative method would be to employ a short tripod (e.g., 18 cm tall, Pringle et al. 2003), but the researcher would need to demonstrate that this would not introduce additional error. Because reflection of incident radiation off leaves introduces considerable error in estimating canopy cover or openness, photographs should be taken during the first two hours after dawn or the last two hours before dark, or at any time on overcast days.

Hemispherical photographs were analyzed using the program Gap Light Analyzer Version 2.0 (Frazer et al. 1999; available for free download at http://www.rem.sfu.ca/forestry/downloads/gap_light_analyzer.htm). This program estimates canopy cover (openness), and incident radiation at the site. The program uses location and season data (the user inputs latitude, elevation, and dates of interest) to plot the sun's pathway through the canopy and thereby estimate incident radiation at the site of interest per unit time. Because we were interested in latitudinal variation in openness and incident radiation on nest sites and how these attributes influenced nest temperatures, we input 90 days into the analysis to approximate incubation time.

Several other specific inputs can be adjusted depending on the analysis required. For example, we calculated a cloudiness index (Kt) for each site for each month (instead of using the default of 0.5) because we were concerned that this could vary appreciably among sites (i.e., one of our sites was in rainforest). We calculated Kt using the formula $Kt = H/H_0$, where H = the amount of global radiation incident at the ground, and H_0 = the amount of extrater-

FIG. 1. Hemispherical photographs from *Physignathus* nest sites in (top) a tropical rainforest site near Cairns, and (bottom) a cold temperate mountain site near Canberra.

restrial radiation incident on a horizontal surface outside the earth's atmosphere (Frazer et al. 1999). We calculated H_0 using Gap Light Analyzer, and we estimated H using the number of sunshine hours per day (Iqbal 1983). For this we used $H = H_0[0.24 + 0.47(n/M)]$ where n = mean sunshine hours, and M = day length. We obtained n and M for each site from the Australian Bureau of Meteorology records (unpublished data). This equation is one of several that allow estimation of global radiation incident at the ground using sunshine hours data routinely collected by meteorology services. While an appropriately calibrated model can estimate absolute incident radiation (or potentially temperature), using the program's defaults will provide a relative index to radiation among sites (see manual).

The combination of hemispherical photography and gap light analysis (HP & GLA) has been used to quantify nest site choice in only two previous studies (Harlow 2001; Shine et al. 2003), but HP has been commonly used to measure gap size and radiation in forestry studies (e.g., Whitmore et al. 1993), and both were recently used to quantify the thermal effects of canopy structure in a habitat selection study of a snake (Pringle et al. 2003). In our research we used the technique to quantify nest site choice in water dragons, a species with temperature-dependent sex determination. Specifically, HP & GLA allowed us to determine how these lizards, which span environmental extremes, were compensating for climate differences to produce viable sex ratios. Our major findings (Doody et al., *in press*), were that both openness and incident radiation intensity at the nest site were both positively related to latitude, minimum and maximum mean monthly air temperatures, and soil temperature. Table 1 (columns 1 and 2) gives an example of the difference in openness between high and low latitude nests (nests at the lowest latitude site averaged around 20% compared to near 50–60 % for the highest latitude sites. A spherical densiometer estimates only canopy openness, while HP & GLA combine to give both openness and incident radiation at the nest site. This distinction is important, because openness is not necessarily a surrogate for incident radiation at the nest site. Two nest sites can have the same openness but very different radiation intensities, as demonstrated in Table 1. The same openness (photograph = Fig. 1, top) produced very different radiation intensities when run through GLA for different latitudes (Table 1, column 1 vs. 3) or different times of the year (Table 1, column 1 vs. 4). Finally, estimating canopy openness using a densiometer does not take into account more proximate shading vegetation such as grasses, whereas HP & GLA does.

In our opinion the technique was superior to the other methods for quantifying nest site choice for the abovementioned reasons. We agree with an anonymous reviewer that our technique would also facilitate developing a mechanistic model of nest temperatures based on openness, radiation, cloudiness, slope, aspect (and any other influences on nest temperatures). The only pitfall of these techniques is the expense. The total cost of our equipment was US $1133, including camera ($675), fisheye lens (FC-E8, $398), memory card 128 MB ($19), and memory card adaptor ($41).

Acknowledgments.—We thank G. Frazer for useful comments with regards to the use of Gap Light Analysis. We also thank R. N. Reed and three anonymous reviewers for improving the manuscript.

Efficacy of Marking Snakes with Disposable Medical Cautery Units

In many situations, marking snakes for recapture purposes is fraught with difficulty. Toe clipping has obvious drawbacks for snakes, and externally attached tags are easily lost via shedding or abrasion against surface objects. Passive integrated transponders (PIT tags) have near 100% reliability and are typically permanent if correctly implanted (Gibbons and Andrews 2004). However, PIT tags are expensive (a minimum of US $3.50 per tag if purchased in large numbers) and in many field studies the recapture rates of snakes are too low to justify their use. Even if funding is unlimited, the limited girth of some neonates and small species precludes the use of PIT tags (Gibbons and Andrews 2004).

Alternatively, snakes can be marked externally by a number of methods. The most commonly-employed technique is clipping of ventral scales anterior or posterior to the vent, in a pattern that varies with the researcher (Brown and Parker 1976; Ferner 1979; Woodbury 1956). These marks are of variable permanence (Shine et al. 1988), and difficulties with readability of marks or mortality of animals often arise if the marks are applied with too little or too much enthusiasm. Clipping scales leaves an open wound subject to possible infection, and marking small snakes is especially difficult (Weary 1969). Freeze-branding has been used by some researchers (Lewke and Stroud 1974; Measey et al. 2001), but this method requires availability of liquid nitrogen, Freon, or similar fluids that may be difficult to transport in field situations.

Heat branding has been used to mark reptiles and amphibians by a number of researchers (Clark 1971; Ehmann 2000; Ferner 1979). Methods of branding have been extremely varied, and equipment has included pyrographic needles (Weary 1969), resistance wire heated by Bunsen burners (Clark 1971) or by electricity (Ehmann 2000), and soldering irons (Ehmann 2000). The majority of this equipment has been improvised from a variety of materials, a task that may be beyond the abilities of the typical herpetologist. These units may also require electrical current from a wall socket, or require use of bulky and/or potentially explosive equipment to heat wires.

Herein, we report on the use of disposable medical cautery units ("Aaron Medical Change-A-Tip cautery units;" Aaron Medical, St. Petersburg, Florida 33710, USA; www.aaronmed.com) as an efficient means of marking snakes. These units are small, inexpensive, field-portable, and capable of quickly and precisely marking even very small snakes. Marks on most species are easily seen for at least two years.

Medical cautery units are designed for a variety of surgical applications and are available in two temperature classes. We have successfully used both high-temperature units (1204°C; ~US $25, available with two different handle styles [one operates on 2 C alkaline batteries, the other on 2 AA alkaline batteries]) and low-

Fig. 1. Medical cautery units used to heat-brand snakes. From top to bottom: high-temperature, 2 CC battery handle; high-temperature, 2 AA battery handle; low-temperature, 1 AA battery handle.

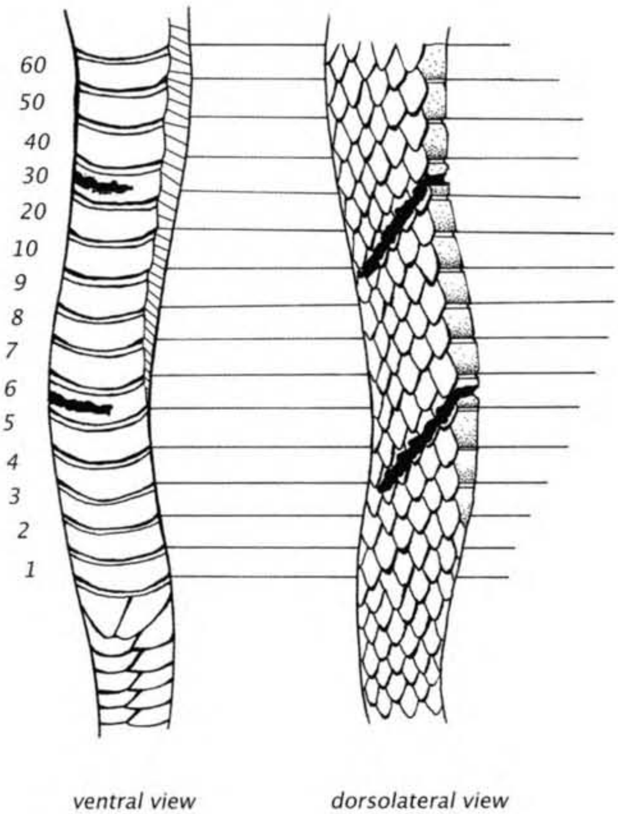

FIG. 2. Illustration of a snake heat-branded with ID # 36. For each mark, we branded the anterior portion of the ventral scale and extended the mark diagonally onto adjoining lateral scales. Illustration drawn by Rebecca Taylor.

temperature units (704°C; operates on 1 AA alkaline battery; ~US $20) designed for ophthalmological applications (Fig. 1). Both units are small and field-portable (Fig. 1). We have used individual units for over a year, marking hundreds of snakes. We replace broken/worn out tips (US $3.50 each) as necessary. Batteries last longer when marking small snakes, but in general batteries must be replaced fairly frequently. Due to the high temperature of the cautery units, marks should be applied with caution whenever fresh batteries are used.

From June 2002 to May 2005, we used medical cautery units to individually mark snakes as part of a long-term mark-recapture study of semi-aquatic snakes on the Department of Energy's Savannah River Site in the upper coastal plain of South Carolina. We also marked a smaller number of individuals of other species, which were not part of any extensive mark-recapture study, to demonstrate the utility of this technique for small and terrestrial species. On each snake, we branded 1–3 ventral scales anterior to the anal plate, forming a unique numerical code (Fig. 2). For each mark, we branded the anterior portion of the ventral scale and extended the mark diagonally onto adjoining lateral scales. We used high-temperature cautery units to mark medium and large snake species, such as Black Swamp Snakes (*Seminatrix pygaea*), Cottonmouths (*Agkistrodon piscivorus*), Racers (*Coluber constrictor*), watersnakes (*Nerodia* spp.), and Timber Rattlesnakes (*Crotalus horridus*), and low temperature units to mark juveniles and small species (e.g., *Cemophora coccinea*, *Lampropeltis triangulum*, *Tantilla coronata*). We found heat branding to be faster than traditional scale clipping for small-bodied snakes.

TABLE 1. Summary of recapture (RC) data for snakes branded with disposable medical cautery units on the Savannah River Site, South Carolina.

Species	N	RC Interval Range (days)	Mean RC Interval (days)
Seminatrix pygaea	105	5–784	320
Agkistrodon piscivorus	37	9–778	259
Coluber constrictor	22	9–785	135
Nerodia fasciata	32	5–1058	183
Farancia abacura	8	4–744	187
Lampropeltis triangulum	3	32–420	164
Elaphe obsoleta	3	41–201	127
Tantilla coronata	2	18–576	—
Crotalus horridus	2	14–59	—
Thamnophis sauritus	1	221	—
Nerodia taxispilota	1	41	—
Cemophora coccinea	1	27	—
Lampropeltis getula	1	26	—
Heterodon platirhinos	1	19	—
Regina rigida	1	17	—

An important assumption of capture-mark-recapture studies is that marks are permanent. In the field it is virtually impossible to determine if brands may be lost in some individuals or species, unless a second marking technique (e.g., PIT tags) is used or researchers can maintain a 100% recapture rate in the field. Alternatively, a laboratory colony of snakes can be maintained to determine mark retention rates over time. We chose this second method to asses the reliability of the brands. In spring 2002, we marked 36 neonate *Antaresia childreni* and *A. maculosa* from four different litters, and have kept them in the laboratory since that time (minus four individuals that were sacrificed for various reasons).

We have recaptured 220 heat-branded snakes of 15 species (Table 1) on the Savannah River Site, suggesting that this technique works well for a variety of taxa. The longest recapture interval was 1058 days, and we recaptured individuals of nine species after an interval > 200 days (Table 1). Additionally, long-term recaptures in small species (e.g., *Tantilla coronata*, 576 days; *Lampropeltis triangulum*, 420 days) attest to the effectiveness of marking delicate snakes with low-temperature cautery units. In general the brands were readily observable, even after greater than two years between captures and bouts of substantial growth (e.g., *Agkistrodon piscivorus*, grew 30.1 cm snout–vent length [SVL]; *Seminatrix pygaea*, grew 16.4 cm SVL). Similarly, the brands on *Antaresia childreni* and *A. maculosa* have remained obvious and readable in the laboratory for over three years, even as the snakes have tripled in length and increased many-fold in mass: no snake displayed marks that were appreciably faded. In combination, these results demonstrate that heat-branding with medical cautery units is an effective, dependable, and inexpensive technique for multi-year mark-recapture studies of snakes.

Acknowledgments.—We thank T. Madsen for demonstrating his system for marking ventral and lateral scales on snakes. We thank X. Glaudas and C. A. Young for capturing and processing some of the snakes. The procedures used in this study were approved by the University of Georgia animal care and use committee (A2003-10024) and the South Carolina Department of Natural Resources (Collection permits: 56-2003, 07-2004). Research was supported by the U.S. Department of the Interior (Fish and Wildlife Service, Division of Scientific Authority), and manuscript preparation was aided by the Environmental Remediation Sciences Division of the Office of Biological and Environmental Research, U.S. Department of Energy through Financial Assistance Award no. DE-FC09-96SR18546 to the University of Georgia Research Foundation.

An Inexpensive Video Surveillance Technique for Wildlife Studies

KYLIE A. ROBERT
School of Biological Sciences and Institute of Wildlife Research
Heydon-Laurence Building (A08), The University of Sydney
NSW 2006, Australia
e-mail: kylie_robert@hotmail.com

Most wildlife behavioral studies require time consuming direct observations of animals (Altmann 1974) or the use of expensive closed-circuit television (CCTV) cameras and time-lapse video equipment (Wratten 1994). Direct observation of animals is limited by how practical observations are of the species and how easily the species is habituated to an observer (Stewart et al. 1997). The use of video applications in wildlife research has been well documented as a useful technique (Pulliainen 1971; Stewart et al. 1997; Sykes et al. 1995; Wratten 1994) and video surveillance equipment has been used increasingly in studies (Hughes and Shorrock 1998; Jury et al. 2001; McQuillen and Brewer 2000; Roberts and Anderson 2002; Shivik and Gruver 2002; Stevens 2002). However, the technique has not been exploited to its full potential by biologists, due primarily to the high initial cost and length of time to extract data from cassettes (Stewart et al. 1997; Sykes et al. 1995). Time-lapse video is widely used by developmental biologists (Kulesa and Fraser 1998; Peppo et al. 2001; Rezaie et al. 2002) but has enormous scope in applications for wildlife research and until recently has been cost prohibitive. The advantages of a video surveillance system include gaining a permanent record of events that can be replayed as many times as necessary to retrieve data, reduction in observer bias and missed observations, easy habituation by the study animal and the ability to document events that are not easily detected using direct observations. Video surveillance can be used to record activity at a focal site (such as entrance or exit to a shelter site or burrow, the removal of baits by target and non-target species), identify individuals, document predation events, and detect nocturnal, crepuscular or elusive species (Brown 1997; Deufel and Cundall 1999; Stewart et al. 1997; Tobler and Schwierin 1996).

Equipment and set-up.—I used inexpensive miniature monochrome (MINI-M20A) video surveillance cameras attached to an existing PC computer via a 4 channel PC digital surveillance recording system (Go Video DVR4, PCI PC capture card and software) available from Allthings Sales and Service (Kelmscott, Western Australia; www.allthings.com.au). Allthings Sales and Service economically and reliably ship worldwide via airmail or EMS speed post, with typical airmail rates to the USA for a 0.5–2kg package ranging from $US 8 to $27 depending on weight. The entire system can be purchased as a complete package and attached to an existing IBM compatible computer from as little as $US 210; the system (discussed below) consists of a 4 channel PCI PC capture card, software, 4 monochrome cameras, and a Plug-in DIY AV 20 meter cable/adaptor set for 4 cameras. Several optional color camera upgrades are also available from $US 60 to $140. Alternatively, each component can be purchased separately and a system

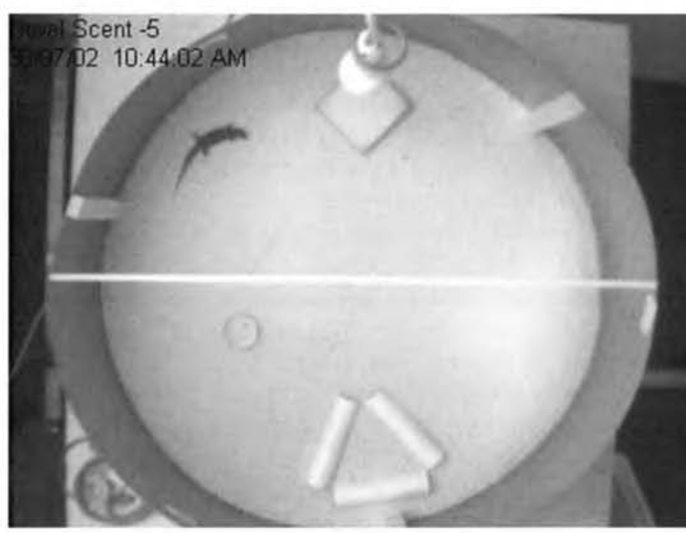

Fig. 1. Snapshot image of experimental enclosure showing camera identification, date and time display.

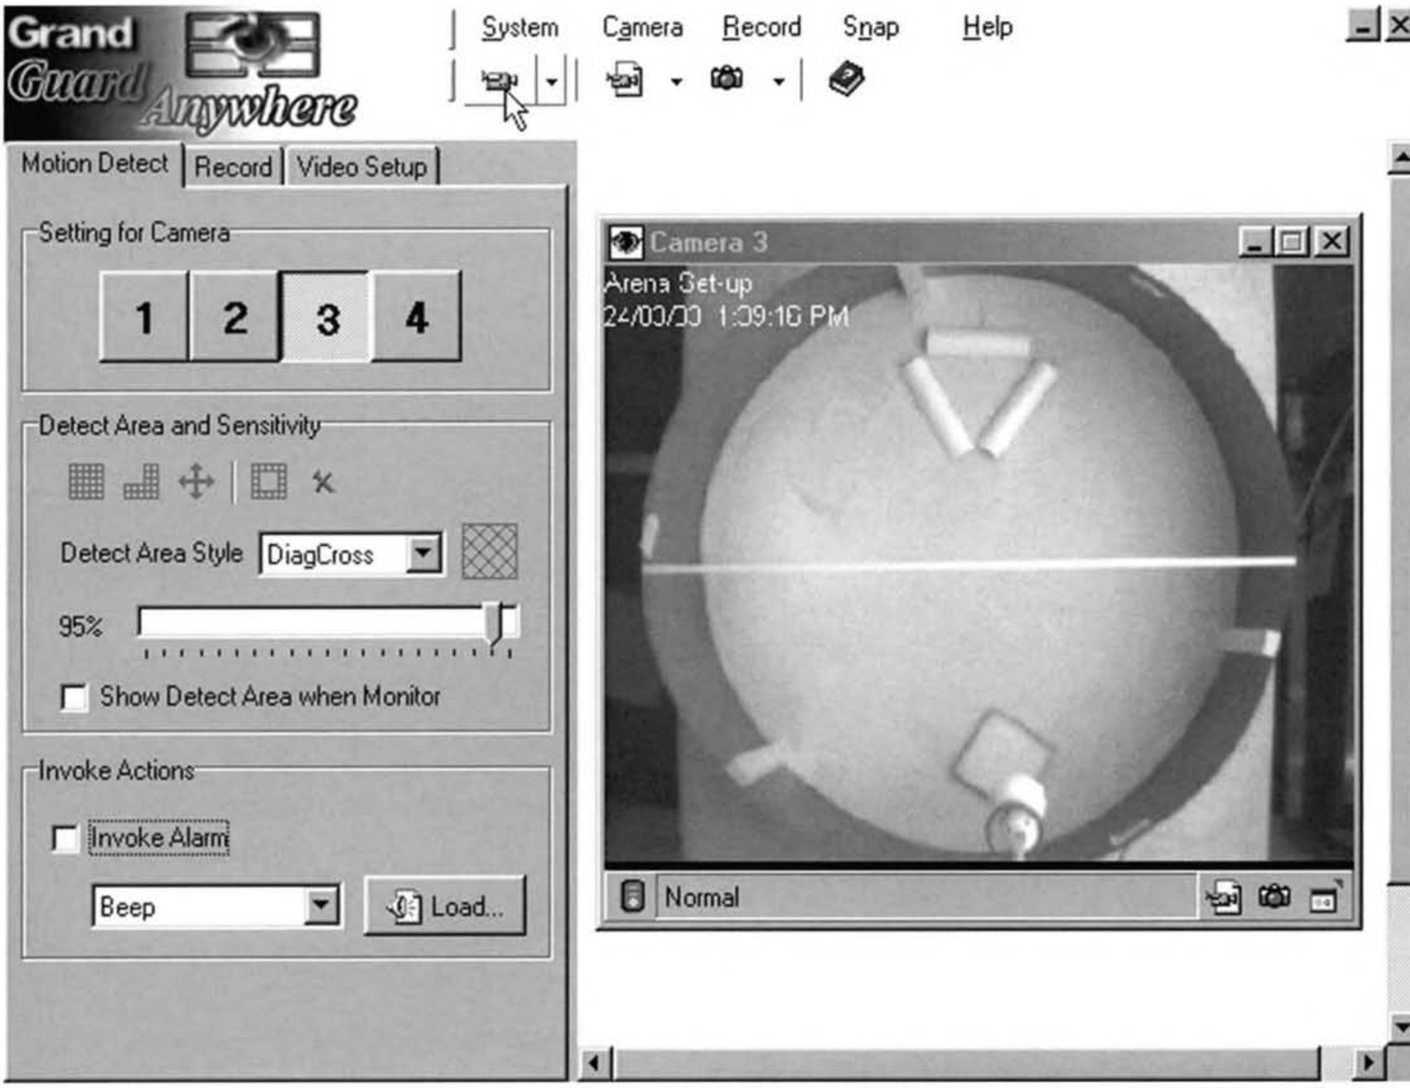

FIG. 2. On screen view of one camera (1–4 cameras can be viewed simultaneously) with set-up menu for motion detect.

built to suit individual or experimental needs. By comparison, quotations supplied by closed circuit television and surveillance system specialists for the identical system ranged from $US 1,782 to $4,048.

Equipment details.—Go Video-DVR4 consists of a PCI PC capture card and Grand Guard Anywhere software (Grandtec, Taiwan) that allows connection of up to four video cameras (capture cards are also available for up to 16 cameras) to display/record simultaneously on a IBM compatible PC computer. The surveillance system is motion sensitive, with adjustable detection sensitivity for each channel (if continuous recording is required motion detect sensitivity is set at 100%). Areas not to be observed or disregarded for motion detect can be defined by masking an area onscreen and audible warnings can be set for each channel to notify of movement. Each video input can be adjusted for brightness, contrast, saturation, hue, image quality and configured to record camera identification, date and time. The system allows high resolution recording [384 lines (H) × 288 lines (V) resolution or 110,592 pixels per camera] in comparison to conventional 4 channel quad/VCR recording system [VHS VCR: 160 lines (H) × 288 lines (V) resolution or 46,080 pixels per camera; SUPER-VHS VCR: 265 lines (H) × 288 lines (V) resolution or 76,320 pixels per camera]. Video capture rate is 3–5 frames/sec and is dependent upon computer hardware, number of channels in use, and image size. The frame rate can be increased when being replayed to speed up data gathering. Video is captured as AVI files that can be compressed and saved on the computer hard drive for later analysis. A snap shot option captures still images that can be saved as BMP or JPEG images (Fig 1). The system requires a Pentium 200 microprocessor or faster (Pentium 500 or above recommended by manufacturer), PCI 2.1 compliant mother board, at least 64 MB RAM, Microsoft windows 95 or 98 operating system (capture cards are also available for other Windows operating systems, e.g., ME/2000/XP), one PCI slot, and at least 1GB hard disk space per camera.

MINI-M20A cameras are 1/4-inch low smear image sensor monochrome infrared sensitive surveillance cameras with wall or ceiling mount. They come complete with a 3.6 mm lens, but you can choose the lens that best suits your application.

Plug-in DIY AV 20 m cable/adaptor set includes 20 m of audiovisual cable with all the appropriate molded plugs and sockets required for self-installation.

I tested the video set-up using three separate temperature controlled rooms with cameras mounted to the ceiling ca. 1.3 m above experimental enclosures. I placed medium-sized scincid lizards (*Eulamprus tympanum,* 130–150 mm total length) in 1 m diameter enclosures and recorded the lizards' behavior from 0900 to 1700 h on 95% motion detect (Fig. 2). To test the suitability of the set-up for my purposes, I chose to record position of lizards at 5 minute intervals and estimate activity rate by dividing the enclosures in half with a piece of string and recording the number of times the lizard crossed this line (Fig. 2). The clarity of the picture was more than sufficient for the purpose of this experiment. Each AVI file was compressed (zipped) and saved on compact disc for storage and later analysis. The software included with the surveillance package (Presto! Video Works, Newsoft®) was used for video replay and data collection. During replays, the video frame rate was adjusted to 10 frames per second to speed up the scoring process.

Discussion.—The use of miniature cameras and video surveillance software has wide applications for wildlife and behavioural research. Previously, the major disadvantage with this technology has been the initial set-up cost and the time required to playback video tapes for data collection. New technologies have developed inexpensive cameras and computer software equipped with motion detect sensing to eliminate periods of no activity that in turn speed up data retrieval upon playback. A compact disc burner is recommended to burn all compacted (zipped) AVI files for storage and later data analysis to reduce storage requirements on the hard drive and to ensure a safe back-up should a different analysis or further analysis be required.

The entire set-up could be modified or components upgraded to collect field data by running on a computer in weather proof housing or a laptop computer with a USB video capture box using a portable power source (generator, batteries, or solar power). Cameras can be placed in weatherproof housings or upgraded to outdoor surveillance cameras. There is also the option of wireless cameras and receivers.

A video surveillance technique for wildlife has not been exploited to its full potential in behavioural and ecological studies despite a history of documented use in such studies (Sykes et al. 1995; Wratten 1994). Rapid improvements in low cost equipment have made the technology readily accessible to biologists, and may result in more widespread application of the technique.

Acknowledgments.—I thank Kevin Forknall from Allthings Sales and Service for technical advice and R.N. Reed for providing useful comment on the manuscript. Lizards were collected under scientific licence from the New South Wales National Parks and Wildlife Service (B2082) and research was approved by The University of Sydney Animal Care and Ethics Committee (L04/11-99/3/3042). The project was supported in part by an Ethel Mary Read Research Grant from the Zoological Society of New South Wales and a Joyce W. Vickery Scientific Research Grant from the Linnean Society of NSW to K.A. Robert.

Numerous capture-recapture studies of amphibians have used the unique color patterns of certain amphibian species to "mark" individuals, recording pattern information with sketches, photographs, or a coding system (Andreone 1986; Forester 1977; Gill 1978; Kurashina et al. 2003; Marvin 1996; Nace et al. 1973; Nijhuis and Kaplan 1998; Tilley 1980). Such non-invasive techniques are preferred over physical alteration of an animal, which may include toe-clipping, visual implant elastomer, or other added marks (Bailey 2004; McCarthy and Parris 2004; Murray and Fuller 2000; but see Funk et al. 2005). Regardless, bias associated with any individual identification method should be assessed and reported, though this has been infrequent in amphibian capture-recapture studies (but see Bailey 2004; McCarthy and Parris 2004; Muths et al. 2000).

For long term capture-recapture studies to be successful, marks must not be lost over time; this is assumed to be true for natural patterns that serve as marks (Gill 1978). More importantly, marks should not be overlooked or misidentified by observers. Reduction of observer bias in mark recognition is paramount in studies that estimate population sizes and document long term trends.

The goals of our study were to: 1) quantify error rates in individual identification through specific pattern mapping approaches; 2) address sources of error by developing a modified pattern mapping method; 3) compare bias associated with these two methods and identify which method minimizes observer bias in both pattern mapping in the field and individual identification in the lab; and 4) determine the search effort necessary to find all individuals in a dataset. We assessed bias in pattern matching of the Spotted Salamander (*Ambystoma maculatum*), a mole salamander with conspicuous and distinctive yellow spot patterns.

Materials and Methods.—We used data from March–April 2002 and 2004 for this study. To capture migrating spotted salamander adults we used artificial cover objects (61 × 122 cm plywood boards) and a drift fence completely encircling Laura's Pond, a semipermanent fishless pond in Beltsville, Maryland (USA). We digitally photographed the dorsal patterns of each salamander on a flat surface using a Nikon® Coolpix 995 digital camera, in the shade using the integrated flash to reduce glare. We did not sedate or restrain salamanders.

Between 03 March and 08 April 2002, we employed a multi-parameter (MP) method of pattern mapping (Table 1) based on a modification of the Loafman method (Loafman 1991). All pattern mapping was done in the field. We counted any spot > 1 mm spanning two body areas once (in the area which contained the majority of the spot). Twenty observers (2–10 per visit) participated in recording pattern data for 654 salamander captures. We entered and sorted all pattern data in Microsoft® Excel™ spreadsheets; each record represented one capture occasion and was associated with its digital photograph. We used Microsoft® Photo Editor™ to view multiple photographs at once. In the lab, we sorted spot counts by the six body areas (Table 1). Individuals were identified by comparing and matching digital photographs among these grouped records. Of 378 individuals identified, 136 were captured more than once. We noted that for some of these individuals, recorded pattern data varied among capture occasions. Because we had digital photos from each capture, we were able to verify that discrepancies were due not to pattern changes, but rather to errors in field data collection using the MP method.

We tested the hypothesis that the variation in field data recorded using the MP method differed among areas of the body (e.g., head, each leg, and body + tail). We selected at random a set of 50 individuals with multiple captures (mean number of captures per individual = 3.82, range = 2–13), and assessed the variation in recorded spot counts by body area between observations of each individual. We hypothesized that head pattern data would have the lowest observer bias based on Doody (1995), who observed that head patterns often were sufficient to distinguish individual Spotted Salamanders.

We compared the efficiency of the MP method to a reduced parameter (RP) method of pattern mapping (Table 1) which we hypothesized would facilitate pattern mapping in the field and individual identification in the lab. As in the MP method, a spot spanning two body areas was counted only once. Other supporting pattern data also were recorded, including a categorical assessment of the spots anterior to the gular fold [i.e., eye code, where 0 = no spots by either eye, 1 = spot(s) by one eye only, 2 = spot(s) by both eyes; see Nace et al. 1973], eye spot symmetry (yes/no) and gular spot symmetry (yes/no), where symmetry describes the same number of spots in mirror orientation across an anterior–posterior midline.

To assess laboratory error, we tested whether the method of pattern mapping (MP vs. RP) influenced the ability of observers to identify individuals by matching pattern data and associated photographs. We also tested whether the ability of observers to identify matches varied based on the number of records. Two sets each of 50 and 100 capture records were chosen at random from the 2002 (MP) data; individuals were manifested in these "test datasets" as one record (one capture), or as a set of >1 records (multiple captures or "matches"). The number of matches per dataset was known; individuals were identified and verified in the full set of pattern data. Based on the associated photos, a copy of each file was then altered by one of the authors (EHCG) to show only the parameters pertaining to the RP method (Table 1). Five observers were presented with the same 8 test datasets (2 MP and 2 RP datasets each of 50 and 100 records).

The observers identified matching records in the lab, recording elapsed time between finding matches, as well as total time spent on each test dataset. We created an "observer performance" matrix (modeled after a traditional capture history matrix) where rows represented each salamander capture record, and columns represented the classification results from each observer for each salamander. Classifications were designated as either "correct" (match-

TABLE 1. Descriptions of two pattern mapping methods used to distinguish individual Spotted Salamanders, *Ambystoma maculatum*.

	Method	
Character	Multi-parameter (MP)	Reduced parameter (RP)
Spot definition	Any yellow or orange spot >1.0 mm maximum length or width	Any yellow or orange spot, regardless of size
Body areas counted	Six body areas: 1) total head spot count, 2) total body (torso+tail) spots 3–6) separate counts for each leg	Two body areas: 1) total head spot count, 2) sum of counts from the front legs
Description of head spot pattern	No additional descriptors for head spot location	Additional descriptor codes for head spot location and symmetry

ing records or unique records correctly identified as such) and received a value of "1," or "incorrect" (failure to detect matching records when present) and received a value of "0." We combined the observer matrices from all test datasets for each method, and tested whether the binomial probability of correct classification differed between: 1) the two methods (MP vs. RP); 2) the number of records presented to each observer (50 or 100); and 3) observers, using the program CONTRAST (Hines and Sauer 1989). We also calculated the average time to find a match for each method, and estimated the number of searches through a full dataset necessary to identify all matches correctly by $(1\text{-p})^t$, where p is the probability of correct classification and t is the number of searches by one observer.

We employed the RP method during 08 March to 14 April 2004 because fewer parameters were collected, thereby reducing field handling time per salamander. We recorded a total of 592 capture occasions of Spotted Salamanders. One observer searched the data for matches, eliminating all secondary captures from the data set (leaving only presumed initial captures and those records representing salamanders presumed to have been captured only once) before searching again. We counted the actual number of search iterations necessary to identify all individuals and compared this to our estimated number of iterations based on the average classification probability of five observers from the test datasets.

Results.—Within the 50 Spotted Salamander individuals with multiple captures from the preliminary assessment of the MP method, the mean and variation in recorded spot counts for the head (mean = 0.48, var = 0.51, range = 0–5 spots) and legs (mean = 0.88, var = 0.58, range = 0–3 spots) were smaller across capture occasions than for the body (mean = 1.48, var = 1.01, range = 0–6 spots).

Comparing the MP and RP methods in the test datasets, the probability of correct classifications was high for all observers between both method [p_{MP} = 0.97 (SE = 0.005), p_{RP} = 0.96 (SE = 0.005); χ^2 = 0.88, P = 0.35] and the number of records presented to the observers [p_{50} = 0.97 (SE = 0.006), p_{100} = 0.96 (SE = 0.004); χ^2 = 0.51, P = 0.48]. Observers did not differ in their ability to classify records correctly (mean $p_{\text{test datasets}}$ = 0.96; χ^2 = 5.86, P = 0.21), although actual correct classification varied (MP: mean = 80 + 23 %, range = 33 to 100 %; RP: mean = 74 + 27 %, range = 0 to 100 %). Of 1500 total records (5 observers × 2 sets × [100 + 50 salamanders]) in test datasets per method, observers incorrectly classified 52 (3.5%) MP and 60 (4.0%) RP records. The amount of time spent searching for matches did not explain the proportion of correct classifications (Fig. 1). Assuming that the mean observer detection probability (p) does not change as observers find more matches in a dataset, we estimated that a minimum of four searches through the data are necessary to identify all individuals (Fig. 2).

Comparing these results to our 2004 data collected using the RP method, we found that the actual probability of correct classification was less than our estimate (p_{2004} = 0.90 vs. $p_{\text{test datasets}}$ = 0.96, Fig. 2), and the number of iterative searches necessary was greater than our estimate (t = 8 searches, Fig. 3). The probability of incorrect classification decreased over the 8 searches (1-p; Fig. 3).

Discussion.— The MP and RP methods were comparable in efficiency and accuracy in identifying individuals in the lab, and the probability of correct classification was independent of method, number of records, or observer. This suggests that the method of pattern mapping does not affect the ability of observers to match individuals in small datasets, provided that supporting data allows records to be grouped. Observer performance, measured by number of incorrect classifications, was slightly better using the MP

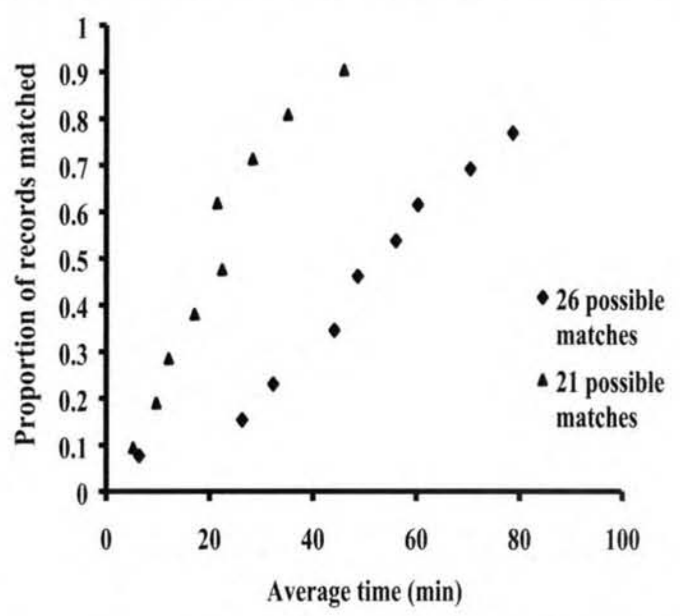

FIG. 1. The proportion of records matched (where a "match" is defined as >1 records representing multiple captures of an individual) vs. time spent by 5 independent observers using Spotted Salamander (*Ambystoma maculatum*) pattern data from Laura's Pond in Beltsville, Maryland, USA. Each series represents one of two replicates from the 2002 test datasets (MP method) with 100 individuals each. One dataset had 21 possible matches, while the other had 26 possible matches. Not surprisingly, a greater number of potential matches present in a data set requires a longer amount of time to identify the complete set of matches.

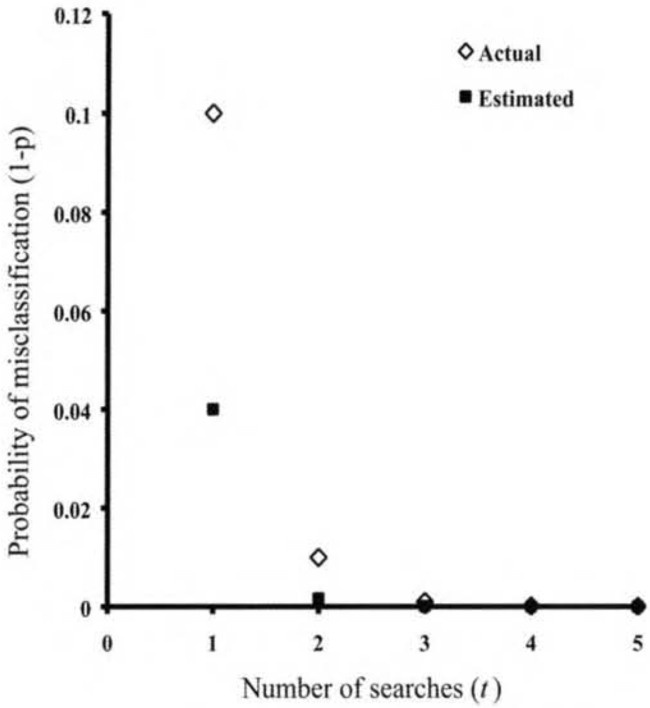

FIG. 2. The estimated (using test datasets) and actual probability (using 2004 field data) of incorrect classification (1-p), or missed matches, in Spotted Salamander pattern data. The number of searches represents iterations necessary for one observer to search a data set and identify all possible individuals, estimated by $(1\text{-p})^t$, where p is the probability of classifying a record correctly and does not change, and *t* is the number of searches. The mean value $p_{\text{test datasets}} = 0.96$ was estimated from 5 independent observers searching 8 test datasets, and the value $p_{2004} = 0.90$ represents the actual classification probability from the first iterative search of the 2004 RP data collected in the field.

method. However, we observed that the RP method reduced the time to handle and record pattern data in the field. This likely reduced stress on the animal, particularly those captured multiple times, and therefore we prefer the RP method.

Inconsistent pattern mapping in the field (field error) prevented some records representing the same individual from becoming grouped when sorted in the spreadsheet, and thus matches within these groups may have been missed. Variation in pattern data over multiple captures of the same individual may have partially resulted from our size-restricted "spot definition" (Table 1) in the MP method; this restriction was removed in the RP method. Field error due to transpositions of spot counts for right versus left or front versus rear leg were eliminated in the RP method by summing spot counts for both front legs. Out-of-focus pictures, poor lighting/contrast, and photos that did not show the entire pattern clearly also could have resulted in missed matches. Problems in field photography were not addressed here, but could be eliminated by using standardized photographic procedures (e.g., Doody 1995; Ravela and Gamble 2004).

To identify all individuals from capture records, we found that multiple searches through the data by one observer were necessary. Eliminating one record from each matching pair in the data set after each search reduces the number of capture records to compare. The number of individuals represented by multiple records in a data set will naturally affect the amount of time necessary to detect all individuals (Fig. 1). In our 2004 data set, 8 iterations of sorting and matching records were necessary to identify all individuals (Fig. 3). However, the presence of a small amount of error in classification may not severely affect the estimates of population size (Miller et al. 2002). An assessment of the relative contribution of the two types of error investigated here (i.e., field error vs. laboratory error resulting from missed matches in the dataset) can contribute to decisions regarding whether a small amount of error in detecting matching records in the lab can be tolerated. Our results suggest that the probability of false matches (classifying records as matches when they are not) is probably small. The probability of incorrect classification fell below p = 0.02 after 3 searches through the data set (Fig. 3), suggesting that fewer searches may not appreciably affect population estimates.

Previous studies have used counted parameters alone (Loafman 1991) or photographs alone (Bailey 2004; Kurashina et al., 2003) to identify individuals using pattern data. Incorporating supporting information with photos or drawings helps to increase the efficiency of identifying individuals (Gill 1978; Nace et al. 1973). We summarize pattern data in spreadsheet software, which allows us to sort the data and group records with similar characteristics (e.g., number of head spots), and then compare photos within groupings. In studies where relatively large numbers of salamander captures are possible, this combination of data types may facilitate the identification of individual salamanders by narrowing the number of records to compare, and digital photos allow the confirmation of matches. This approach is specific to discrete and enumerable pattern features such as spots, though it might be ap-

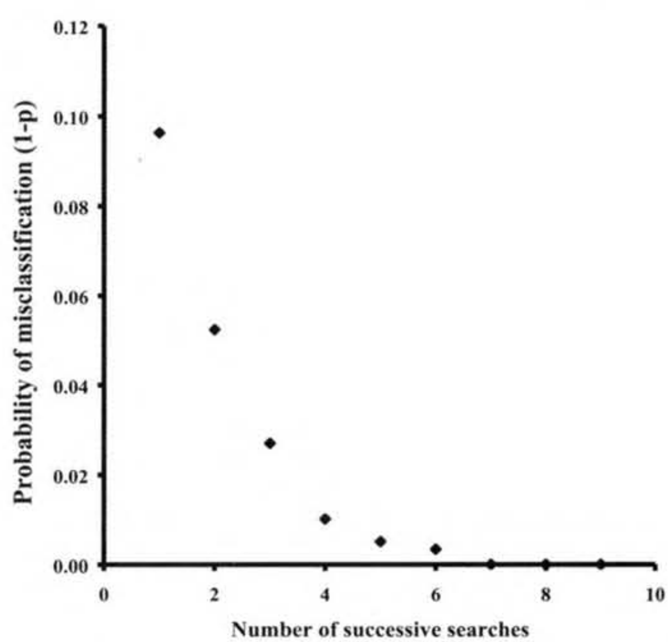

FIG. 3. The observed probability of incorrect classification by the number of searches of the 2004 field-collected data using the RP method. After each search, any records designated as secondary captures were removed from the data set prior to a subsequent search (leaving only presumed initial captures and those salamanders presumed to be observed only once). The probability of incorrect classification (i.e., missed matches) decreases with successive searches through the data. All individuals were identified by the 8th iteration of the successive searches; the 9th search confirmed that no additional matching records were present.

plicable to other elements of pattern. Future advances in technology (i.e., ambystomatid pattern-recognition software, Ravela and Gamble 2004; D. Church, pers. comm.) will automate the process of identifying individuals. Pattern recognition research is progressing in the field of facial recognition (Zhao et al. 2000), and this emerging body of literature (and associated products) can have practical applications for wildlife biology. Even with automated pattern recognition, a subset of computer-determined individuals may require validation using methods similar to the process we present (see also Whitehead 1990; whale fluke identification). Regardless of method, some assessment of bias is useful in evaluating whether a technique violates the assumptions of capture-recapture modeling (specifically 1) that marks are not lost during the period of study and 2) observers can recognize marked individuals, and do not designate marked individuals as new captures). Validation of data subsets can allow investigators to evaluate a marking approach, and thereby qualify the derived estimates of population size or trend.

Acknowledgments.—This project was supported by the USGS Amphibian Research and Monitoring Initiative, Northeast region. Brand names provided in this paper are for information only and do not constitute endorsement by the US Geological Survey. Our manuscript was greatly improved by comments from L. Bailey, S. Doody, L. Gamble, M. Mazerolle, D. Olson, C. Phillips, and two anonymous reviewers. Many thanks to the observers including R. E. Jung, A. Mongeon, T. Plenderleith, and E. Wilson. We also thank W. Crouch for insightful discussions, L. Bailey for suggestions on study design and data analysis, and the late Laura Mazanti for initiating the study of Spotted Salamanders at this study site.

Further Observations of Oviposition in the Surinam Toad (*Pipa pipa*), with Comments on Biology, Misconceptions, and Husbandry

KEVIN C. ZIPPEL
IUCN/SSC Conservation Breeding Specialist Group
25 Spring Street, Union Springs, New York 13160, USA
e-mail: zippelk@yahoo.com

Although the Surinam Toad (*Pipa pipa*) was originally described in 1758 (as *Rana pipa* by Linnaeus), published information on the biology of this species has been slow to accumulate. The limited information available has been derived largely from preserved materials and observations of a few captive specimens. This note reviews the biology of the species, details original observations on reproductive behavior in captivity, aims to dispel some persistent misconceptions, and offers recommendations for captive husbandry in the interest of stimulating further research.

The Surinam Toad occurs widely throughout northern South America and is certainly one of the strangest and most fascinating of all anurans. From its morphology to its reproductive mode, this species is strikingly different from what we think of as "typically anuran." *Pipa pipa* is extremely depressed (dorso-ventrally flattened) and has a broad, triangular head with several fleshy sensory protuberances, a huge mouth, and tube-like nostrils. These traits combine to produce a bizarre appearance uncannily similar to that of the Mata Mata Turtle, as noted by Rabb (1969) and Armburst (1979). At 10–20 cm body length, their size is equally

HERPETOLOGICAL REVIEW

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2006 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with VISA or MasterCard (account number and expiration date must be provided). Payment should be sent to: Breck Bartholomew, SSAR Membership Office, P.O. Box 58517, Salt Lake City, Utah 84158, USA. Fax: (801) 453-0489; e-mail: ssar@herplit.com.

Future Annual Meetings

2006 — New Orleans, Louisiana, 12–17 July (with ASIH, HL)
2007 — Saint Louis, Missouri (with ASIH, HL)

About Our Cover: *Boiga dendrophila*

Dutch herpetologist Nelly de Rooij (1883–1964) is one of the more remarkable figures in 20th century herpetology, given the obstacles she overcame to establish herself as a scientist. Her most prominent work, "The Reptiles of the Indo-Australian Archipelago" (Leiden, 2 vols.; 1915, 1917), remains the definitive source on the area nearly a century later. Under then-existing Dutch law, she was not allowed to attend university following high school, so she went to Switzerland. She completed her Ph.D. degree in 1907 at the University of Zurich. (Additional biographical details are provided in Adler's "Contributions to the History of Herpetology." SSAR Contributions to Herpetology, No. 5, Oxford, Ohio, pp. 76–77).

The artist of our cover illustration is Mr. Joan François Obbes (1869–1963), a well-known Dutch artist of botanical and zoological subjects. He drew all 249 illustrations in De Rooij's classic book. Obbes was a naval officer and a cartographer for the Department of the Navy, spending a short time in the Netherlands East Indies during the Atchin War near the end of the 19th century. Later, he prepared numerous illustrations for the Amsterdam Zoological Museum, including those for the De Rooij volumes, as well as for the first ten volumes of "The Fishes of the Indo-Australian Archipelago" (issued 1911–1953).

With reference to Obbes' work, it has not been previously recorded that at least some of his line drawings used in the De Rooij volumes, including the figure shown on this page, were based on watercolors likely prepared using live specimens shipped to him from Java. In this case, the original watercolor (depicted on our cover) measures 29 × 41 cm and is in the private collection of Kraig Adler; it has not been published previously.

Our cover subject, *Boiga dendrophila* (Mangrove Snake), is a relatively well-known snake today, both to herpetologists and to the hobbyists who maintain this species in captivity. The cover specimen is typical of the many-banded Javanese race (*B. d. dendrophila*), referred to in the De Rooij work as *Dipsadomorphus dendrophilus*. The most recent review of this species is by Gaulke et al. (2004. Herpetofauna 25[143]:5–16), who describe *B. d. levitoni* from the Philippines, and recognize a total of nine subspecies. See also Vogel (2000. Sauria 22[1]:27–43). The genus *Boiga* comprises 33 presently recognized species, several of which have been described within the last decade. For a current checklist, as well as pdf reprints of several recent papers, consult Gernot Vogel's website:

<http://www.gernot-vogel.de/index.php?target=checklist>

Editor's note.—We are grateful to Kraig Adler for providing the cover illustration and portrait of De Rooij, as well as to L. B. Holthuis for biographical information and portrait of Obbes.

Figure 76 (page 198) from De Rooij (1917), based on the watercolor drawing by Obbes reproduced on the cover.

SSAR BUSINESS

Announcing the SSAR Relations with Herpetologists at Zoological Parks Committee Forum

http://www.ssarherps.org/forum

Forum Goals.—The primary purpose of this forum shall be to facilitate communication between academic and zoo herpetologists regarding areas of mutual interest. The forum should serve as a platform for discussing ideas about basic research, collaborative field projects, etc., and also as a "bulletin board" for making known various resources available to both parties.

Criteria for Membership.—Membership is exclusive, and restricted to those individuals who are affiliated with a university, zoological park or scientific or government institution. General public intrusion will not be allowed. When registering, it is helpful to use your last name as your username. Also, you are required to list your institutional affiliation.

Committee Mission Statement.—The Relations with Herpetologists at Zoological Parks Committee will encourage and facilitate participation and communication among members of the Society for the Study of Amphibians and Reptiles and zoo herpetologists for the enhancement of both parties.

General Goals.—1) Increase participation of zoo herpetologists in the SSAR through membership and events; 2) Strive to make various zoo and university resources readily known and accessible to zoo and academic herpetologists; 3) Assist and direct communication between members of both parties; 4) Disseminate information regarding current and/or potential studies of interest to both parties; 5) Identify possible opportunities for collaborative research.

SSAR Henri Seibert Awards for 2006

The Henri Seibert Awards were initiated in 1992 to provide recognition for the best student papers presented at the annual meeting of the SSAR. To be eligible, the presented paper must be the result of research conducted by the individual making the presentation. The research must have been conducted while the student was enrolled in either an undergraduate or graduate degree program. Please refer to Herpetological Review 28(4):175 and the SSAR website for recommendations to students entering the Henri Seibert Competition. Students entering the competition must be members of SSAR. The presentations will be judged by the SSAR student prize committee. One Henri Seibert Award of US $200 may be given in each of the following **four** categories: **Systematics/Evolution, Ecology, Physiology/Morphology, and Conservation**. Students may win the award only one time. Please indicate the appropriate category for which you are applying on the abstract submission form. Announcement of winners will be made at the **SSAR Business Meeting**. All participants should be present at the business meeting. Contact Margaret Gunzburger for further information, margaret_gunzburger@usgs.gov.

NEWSNOTES

The Libraries and Specimen Collections of Dr. Garl Gans

Dr. Carl Gans retired as Professor of Biology and former Department Chair at the University of Michigan in 1997, moving to the University of Texas in Austin as Adjunct Professor. Since then he has donated his extensive libraries, scientific correspondence, and specimen collections in the field of herpetology to various universities and research institutions. These donations were made with the express purpose of making these materials available for study and research by students and scientists. Gans, who is perhaps best known as editor of the *Biology of the Reptilia* series is a former President of SSAR. He transferred sponsorship of the *Biology of the Reptilia* to SSAR in 1995, and Volume 20 in the series is now being readied for publication. Following is a synopsis of the distribution of the Gans libraries and collections.

The Herpetology Library of Carl Gans.—Now at the Ben-Gurion University of the Negev (Israel), comprising more than 20,000 publications, including a number of rare books. Contact: Librarian (e-mail: libboker@bgu.ac.il) or Curator Amos Bouskila (e-mail: bouskila@bgu.ac.il).

The Scientific Correspondence of Carl Gans.—Ben-Gurion University of the Negev (Israel), comprising 13 five-drawer filing cabinets of scientific correspondence between Gans and colleagues with whom he collected specimens on five continents and co-authors of his many publications, including the many volumes of the Biology of the Reptilia. Included are extensive slide and film collections used in his studies of functional morphology. Contact information as above.

The Lancelet Reprint Collection.—Scripps Institute of Oceanography, University of California, San Diego (USA), comprising ca. 2900 items published between 1774 and 1995. Contact: Peter Brueggeman, Head Scripps Librarian (e-mail: Pbrueggeman@ucsd.edu).

Bound Set of Gans' Publications and Herpetological Specimen Collection.—Department of Herpetology, Museum of Comparative Zoology, Harvard University, Cambridge (USA). The Department library has a bound set of all of Gans' published works; these are available for use by students and visiting scholars. Herpetological specimens number approximately 2500, obtained during the period 1960–1980 from Bolivia, Costa Rica, Nicaragua, Mexico, Kenya, Tanzania, and Somalia. Contact: Curator James Hanken (e-mail: hanken@oeb.harvard.edu) or Collection Manager José Rosado (e-mail: jrosado@oeb.harvard.edu).

Herpetological Specimen Collection.—Carnegie Museum of Natural History, Pittsburgh (USA), comprising about 4000 specimens collected by Gans between 1944 and 1998. Contact: Stephen P. Rogers, Collection Manager (tel. 412/622-3255).

Specimen Collection of Amphisbaenia.—Division of Amphibians and Reptiles, Field Museum of Natural History, Chicago (USA). The collection of 1450 specimens, representing over 75 species, was accumulated over three decades by Gans. In addition to pickled specimens, the collection includes series of histological slides, and skeletal and cleared/stained specimens. Contact:

Maureen Kearney, Associate Curator (e-mail: Mkearney@fieldmuseum.org).

Specimen Collection of Uropeltid Snakes.—Department of Herpetology, California Academy of Sciences, San Francisco (USA). The collection of 1824 specimens includes seven of the eight recognized genera and 31 of the 47 known species. It is considered the most comprehensive uropeltid collection in the world. Contact: Jens Vindum, Collection Manager (e-mail: jvindum@calacademy.org).

Reprints Available for Distribution.—Reprints of many of Gans' publications are available. Several volumes of the *Biology of the Reptilia* are available for sale. List of these publications and instructions for requests may be found at:

<http://wwwtest.utexas.edu/tmm/vpl>

Leidy Award Presented to David Wake

On 23 January 2006, The Academy of Natural Sciences (Philadelphia) named a Berkeley scientist who first called attention to the worldwide disappearance of amphibians to receive its prestigious award named for one of the first scientists to call attention to dinosaurs.

Dr. David Wake, professor of integrative biology and curator of herpetology at the University of California, Berkeley, received the Joseph Leidy Award at a ceremony at The Academy of Natural Sciences in February. Wake has studied amphibians for more than 40 years. "We selected Dr. Wake for the award in recognition of his ground-breaking work in conservation biology, with a particular focus on the worldwide disappearance of amphibians and for his many outstanding contributions to systematics and evolutionary biology," said Academy President and CEO Dr. D. James Baker.

Established in 1923 in honor of Dr. Joseph Leidy (1823–1891), anatomist, paleontologist and Academy president, the award consists of a bronze medal and a $5,000 prize. Leidy helped popularize dinosaurs when he described the first dinosaur discovered in America, *Hadrosaurus foulkii,* which became the first mounted dinosaur when it went on display at the Academy in 1868. Past recipients of the Leidy medal include ornithologist James Bond, biologist G. Evelyn Hutchinson and entomologist Edward O. Wilson.

SSAR congratulates Dr. Wake on this recognition.

MEETINGS

First Announcement: 8th Conference of the Herpetological Association of Africa 24–27 November 2006

Herpetologists are invited to join us for the 8th Conference of the Herpetological Association of Africa (HAA), to be hosted by North-West University in Potchefstroom, South Africa in 2006. The HAA is the premier herpetological association on the African continent and publishes African Journal of Herpetology. The 2006 Conference will span four days, including three days of sessions and a special workshop on amphibian declines. The tentative registration fee is R750 for professionals and R600 for students, about US $125 and US $100, respectively. Registration includes attendance at all sessions, lunch and tea breaks, three evening social events, and all conference materials. Accommodation will be available on the North-West University campus, will be within easy walking distance of the sessions, and will be reasonably priced (approx. US $25 per night). Social events will include a braai (barbecue), a banquet, and, for the brave, a mampoer tasting at a local distillery. Mampoer is a locally-brewed, strong, brandy-like moonshine made from fruit mash. The North-West University in Potchefstroom is less than two hours from South Africa's largest airport, Johannesburg International (JNB). Direct flights from Europe and the United States land daily at JNB, which is served by several rental car companies. A call-for-abstracts for oral and poster sessions will be forthcoming. Sessions will take place on 25–27 November. Digital data projectors will be available for MS PowerPoint slideshows, as will carousel projectors. Additional information can be found at www.wits.ac.za/haa/2006conf.htm. To express interest in attending the 8th Conference of the HAA and to receive the second circular, please download the intention form from the conference website and e-mail the completed form to Ms. Cecile Van Zyl, drkcdvz@puk.ac.za.

SSAR Treasurer Vacancy

The Society for the Study of Amphibians and Reptiles seeks applicants for the office of Treasurer. This is a non-paid position with funds available for work-study assistance. Term length is open-ended. Duties are as follows: maintain fiscal records of the Society; make monetary disbursements; coordinate payment to printers for costs of publications after approval by respective editors; invoice reprint orders; interact with Publications Secretary/Membership Office relative to stocks of publications and counts of current number of members; submit annual report which includes budget request for following year to the Secretary prior to annual meeting of the Board. Membership management, investment management, and IRS reports are not part of current duties. The office provides an important contribution toward continuity of information within the Society, thus, attendance at the annual meetings is mandatory. Individuals interested in the position should contact Kirsten E. Nicholson at knicholson@biology2.wustl.edu no later than 16 July 2006.

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

13–15 April 2006—53rd Annual Meeting of the Southwestern Association of Naturalists (SWAN), Universidad de Colima, Colima, Mexico. Information available at: http://www.biosurvey.ou.edu/swan/ or from Dr. Stanley Fox, SWAN President-elect (e-mail: foxstan@okstate.edu).

20–21 April 2006—Northeast Natural History Conference IX, New York State Museum, Albany, New York, USA. Featured symposium: "Direct and Indirect Effects of Roads on Amphibians and Reptiles." Information: http://www.nysm.nysed.gov/nhc

21–24 June 2006—30th Annual Meeting, International Herpetological Symposium, San Antonio, Texas, USA. Information: http://www.kingsnake.com/ihs/

17–19 July 2006—49th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. New Orleans, Louisiana, USA. Information: http://www.dce.ksu/jointmeeting/.

6–9 November 2006—9th Reunión Nacional de Herpetología México, hosted by the Mexican Herpetological Society. Universidad Autónoma de Nuevo León, Monterrey, Nuevo León, México. Information: http://www.sociedadherpetologicamexicana.com/.

24–27 November 2006—Herpetological Association of Africa 8th Conference. Potchefstroom campus of the North-West University, South Africa. Information available from the conference website: www.wits.ac.za/haa/2006conf.htm.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **María del Rosario Castañeda** or **Michele Johnson**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Watersnakes Have Unlearned Tendency to Take Smaller Meals

Mammals have been the central focus of appetite studies, and one generalization that has emerged from this work is that meal size is strongly influenced by learned satieties. However, the trophic biology of snakes is dramatically different from that of mammals, as snakes are precocial soon after birth or hatching, consume prey whole, and take large meals much less often than mammals (who eat small meals multiple times daily). The authors performed an experimental study using the northern watersnake (*Nerodia sipedon*) to determine the consequences of these traits on meal size in neonates at their first feeding episode. In the first experiment, neonates were presented with either an abundance of small prey ($N = 21$) or a single huge ($N = 19$) prey item, and results showed that the meal sizes of animals in the small prey group were significantly lower than those in the huge prey group. Further, to determine where along the prey size axis snake feeding behavior changed, a second experiment in which neonates were assigned to one of four groups (huge, large, medium, or small prey; $n=10$ per group) was performed. This experiment showed that when the average relative prey mass (RPM) was 20% of the snake's size or less, total meal size was ~27% RPM, but when relative prey mass was 40%, snakes consumed a single prey item of approximately 40% RPM. Therefore, this study indicated that when hungry snakes had a choice of how much to eat, they selected smaller meals, but when they had no control over prey size, they consumed a huge meal. Because neonates in the study had not previously eaten, this is not the result of learned meal size. The authors also compared their findings to stomach contents of wild-caught snakes, and discussed the implications of meal size on individual fitness.

Andreadis, P. T., and G. M. Burghardt. 2005. Unlearned appetite controls: watersnakes (*Nerodia*) take smaller meals when they have the choice. Journal of Comparative Psychology 119:304–310.

Correspondence to: Paul T. Andreadis, Department of Biology, Denison University, Granville, Ohio 43023, USA; e-mail: nerodia@denison.edu.

Functional Link Between Morphology and Swimming Speed in Tadpoles

Many developmental, behavioral, and morphological differences exist among anuran larvae across predator regimes, but the functional relationship between swimming speed, morphology, and mortality remains unstudied. The authors examined larvae of *Scaphiopus holbrookii* (Eastern Spadefoot), a species that uses ephemeral pools, and *Rana sphenocephala* (Southern Leopard Frog), a species occurring in more permanent sites, to determine differences in activity level, susceptibility to predation by dragonfly larvae, burst speed, and morphology. Tadpoles were collected in eastern Texas as eggs, and all trials were performed in the laboratory. Results showed that *S. holbrookii* tadpoles were significantly more active, were more susceptible to predation, and exhibited slower burst speeds than *R. sphenocephala* tadpoles. Morphometric analyses using digitized landmarks revealed many shape differences (e.g., tail depth and body size) between the species. The authors also found that body shape was significantly correlated with burst speed for both species, with deeper tails and smaller bodies contributing to faster speeds. These traits may help tadpoles not only to avoid predatory attacks, but also might allow them to escape attacks after they are initiated. This morphology-speed relationship may be a general ecomorphological pattern in tadpoles.

DAYTON, G. H., D. SAENZ, K. A. BAUM, R. B. LANGERHANS, AND T. J. DEWITT. 2005. Body shape, burst speed and escape behavior of larval anurans. Oikos 111:582–591.

Predictability of Anuran Community Assemblages Influenced by Anthropogenic Disturbance

A significant amount of research has focused on predicting the species assemblages of given communities, but changes in community structure as a result of human disturbance are poorly understood. The authors investigated leaf litter amphibians in primary (i.e., undisturbed) and secondary (i.e., disturbed) rainforest at Taï National Park in the Ivory Coast to assay the predictability of the anuran communities in these habitats. They established ten 600-m transects (six in primary forest, four in secondary forest) and characterized 25-m subunits of the transects using 14 habitat variables. In 15 months (including both dry and wet seasons), they found 3843 individuals of 24 anuran species. Using Mantel tests to measure predictability of assemblages based on matrices of species distributions, environmental characteristics, and geographic distance, the authors found that when all data were pooled, all pairwise correlations among these matrices were significant. When data were partitioned by season and disturbance regime, they found no seasonal differences, but primary and secondary forests differed substantially. The anuran composition in primary forests could be predicted based on the geographic distances among sites, suggesting local stochastic recruitment from the regional species pool. In contrast, secondary forest communities could be predicted based on environmental characteristics, a result likely due to the restrictive microclimates available in disturbed areas that limit the species that may survive in such sites. The differences in community predictability between primary and secondary forests indicate that human disturbances not only affect species composition, but also might strongly influence community dynamics.

Bias in Sex Ratio Causes Population Extinction in Lizards

A predominant view in population biology holds that fluctuations in adult sex ratio (ASR) are limited by intrasexual competition, yet this hypothesis remains largely untested. The authors used the common lizard (*Lacerta vivipara*) in southern France to determine the consequences of biased ASR for individual and population dynamics. They established experimental populations of juveniles, yearlings, and adults in 12 enclosures and monitored these populations over one year to measure mortality, dispersal via one-way enclosure corridors, fecundity, and body condition. The 12 enclosures contained 6 female-biased populations (4 adult males, 14 adult females) and 6 male-biased populations (14 adult males, 4 adult females). Results showed that while male emigration and mortality did not differ by treatment, females emigrated more frequently in female-skewed populations, and female mortality was significantly higher in male-skewed populations. Increased female mortality under male excess was likely the result of male aggression during mating, as the percentage of females with mating scars and back injuries in male-biased populations was approximately three times that of female-biased populations. Further, fecundity was significantly lower in male-biased populations. Consequently, population size decreased in male-biased populations but increased in female-biased populations. To determine the possible long-term effects of male-biased ASRs, the authors constructed a stage-structured stochastic population model that confirmed a major population extinction risk under male excess.

LE GALLIARD, J., P. S. FITZE, R. FERRIÈRE, AND J. CLOBERT. 2005. Sex ratio bias, male aggression, and population collapse in lizards. Proceedings of the National Academy of Sciences 102:18231–18236.

Bone-by-Bone Skull Morphology of Spade-Headed Amphisbaenian

Amphisbaenians are a group of fossorial, mostly limbless squamates that are difficult to collect and therefore remain poorly-studied. Four basic cranial morphotypes exist within amphisbaenians: shovel-headed, round-headed, keel-headed, and spade-headed, that relate to their different head-first burrowing behaviors. Recent molecular work suggested that these morphotypes are not monophyletic, but may have evolved multiple times in independent lineages. In this study, the authors provided the first detailed cranial description of a spade-headed species, *Diplometophon zarudnyi*. Using nondestructive high-resolution x-ray computed tomography (HRXCT) on a single museum specimen from Saudi Arabia, the authors described the three-dimensional structure of the skull as a whole, as well as each individual cranial element. The authors also compared the detailed cranial anatomy of *Diplometopon* with two other previously described amphisbaenians, the shovel-headed *Rhineura hatcherii* and the round-headed *Amphisbaena alba*, which revealed that similar structures in different taxa were constructed in different ways. This bone-by-bone morphological data may contribute to greater resolution of the amphisbaenian phylogeny.

MAISANO, J. A., M. KEARNEY, AND T. ROWE. 2006. Cranial anatomy of the spade-headed amphisbaenian *Diplometopon zarudnyi* (Squamata, Amphisbaenia) based on high-resolution x-ray computed tomography. Journal of Morphology 267:70–102.

Population Genetics Of Sympatric Garter Snakes

Many evolutionary and ecological factors might influence the population genetic structure of a species, and similar species in the same environment might experience factors leading to parallel patterns of population differentiation. Using microsatellite markers, the authors compared the population structure of two sympatric garter snake species, *Thamnophis elegans* and *T. sirtalis*, around Eagle Lake in northern California, to determine whether sharing a common landscape has led to similar patterns of genetic differentiation in these competing species. Tissue samples were collected from 858 individuals of *T. elegans* (20 populations) and 433 individuals of *T. sirtalis* (13 populations) at 22 sites. Each individual was genotyped at 11 microsatellite loci, three of which were developed for this study. Relative abundances of the species differed, with *T. elegans* being the more abundant, but their effective population sizes and bidirectional migration rates were comparable. Both species also displayed low but significant population differentiation, with *T. sirtalis* exhibiting more differentiation (i.e., a higher F_{ST}) and stronger isolation by distance. Also, large source populations and likely sinks were identified for each species, suggesting that local population extinction and subsequent recolonization are frequent events in the study area. Using two measures of genetic structure, pairwise F_{ST}s for shared populations and bidirectional migration rates, the authors found a weak but significant correlation between the two species, highlighting the important role of landscape and ecological factors in determining population genetic structure.

Manier, M. K., and S. J. Arnold. 2005. Population genetic analysis identifies source-sink dynamics for two sympatric garter snake species (*Thamnophis elegans* and *Thamnophis sirtalis*). Molecular Ecology 14:3965–3976.

Natural Selection on Lizards Across an Ecological Transition Zone

Studying populations that occur across ecological transition zones (i.e., ecotones) provides an opportunity to determine the relative roles of local adaptation and gene flow in the evolution of phenotypic variation. In this study, the author examined how the entire lizard fauna at White Sands National Monument in New Mexico has responded to selection across a common ecotone. Three species of lizards—*Holbrookia maculata* (Lesser Earless Lizard), *Sceloporus undulatus* (Eastern Fence Lizard), and *Aspidoscelis inornata* (Little Striped Whiptail)—were sampled (N = 41–65/species) in white sand and dark soil localities, and the transition zone between the two. Body coloration was determined using spectrophotometric techniques, and genetic variation across the ecotone was characterized by sequencing the mitochondrial ND4 gene. Results showed that the three species displayed convergence of blanched coloration, but that species differed in the degree to which they matched white substrates and in their coloration at the ecotone. Also, patterns of population subdivision as measured by mitochondrial variation differed among the species, with interspecific differences corresponding to varying genetic connectivity across the ecotone. Overall, the species that had the greatest phenotypic response to substrate differences (*H. maculata*) also displayed the strongest population structure, with *S. undulatus* and *A. inornata* exhibiting intermediate and low levels of these traits, respectively. Matrix correspondence tests revealed that coloration corresponded with habitat similarity, but not genetic similarity, for these lizard species. Together, the results indicated that convergent phenotypic evolution reflects divergent selection on the three species, and that adaptation in this community is moderated by gene flow across the ecotone.

Prosauropod Dinosaur Had Variable Life Histories

The long bones of most dinosaurs indicate that these animals had growth and metabolic rates much higher than modern reptiles, and that there was little final size variation among individuals within a species. However, histology of long and girdle bones of a common early prosauropod dinosaur, the large-bodied *Plateosaurus englehardti*, revealed that individual growth rates and life histories of this species were influenced by environmental factors, as in extant ectothermic reptiles. The authors determined that *P. englehardti* specimens from two sites, Trossingen (N = 32) and Frick (N = 9), could be grouped into three categories based on growth cycles of the fibrolamellar bone and the patterns of lines of arrested growth: fast-growth, slow-growth, and fully grown. To their surprise, fully grown individuals spanned the entire size range of the specimens, and fast-and slow-growth individuals covered a large size range as well. Additionally, there was a weak correlation between body size and age. Therefore, growth rate and final size appeared to vary widely among individuals of this dinosaur species, evidence of strong developmental plasticity that contrasts with most other dinosaurs and is a reversal to the ancestral condition of ectothermy. The authors speculated that *P. engelhardti* might represent the first stage of the evolution of endothermy in dinosaurs.

Sander, P. M., and N. Klein. Developmental plasticity in the life history of a prosauropod dinosaur. Science 310:1800–1802.

Seasonal Differences In Rattlesnake Hormones

Closely-related species often exhibit marked variation in mating systems, even when they occur in sympatry. One example of this situation involves *Crotalus atrox*, the Western Diamond-backed Rattlesnake, and *Crotalus molossus*, the Black-tailed Rattlesnake,

which co-occur in the southwestern United States and Mexico, but differ in the frequency and timing of their mating periods. The authors examined these species to determine whether males display seasonal patterns of plasma sex steroids and whether these hormones are most abundant during each species' mating season. Using radioimmunoassay techniques, they measured testosterone, 5α-dihydrotestosterone, and 17β-estradiol in blood samples collected at monthly intervals from wild-caught adults of each species. Results showed that the annual cycles of these hormones significantly differed in the two rattlesnake species, with *C. atrox* displaying a bimodal hormone abundance pattern that corresponded to its two mating seasons, while *C. molossus* had a single hormone peak during its single mating season. The authors also discussed between-year differences in hormone levels, the influence of body condition on sex hormone production, and possible causes of the hormone cycles observed in this study.

Reproductive Isolation of Salamander Morphs

Reproductive isolation (RI) is a prerequisite to sympatric speciation, but few studies have investigated potential incipient species. The authors performed field observations of two natural populations of facultatively paedomorphic salamanders (*Ambystoma talpoideum*) in which individuals become either terrestrial metamorphic adults or aquatic paedomorphic morphs depending on the environment experienced during development. Both morphs may coexist in the same population, but there are a number of morphological, behavioral, and ecological differences between the two. The authors used drift fences and pitfall traps surrounding each population and minnow traps in ponds to measure temporal and spatial breeding separation and body-size variation between morphs. Results showed that paedomorphic males and metamorphic females have essentially no reproductive isolation, but that metamorphic males and paedomorphic females had considerable RI. This asymmetry in RI might be the result of factors such as morph abundance, rainfall, and depth of breeding ponds. Spatial isolation played a more important role in RI than temporal isolation, mostly because the morphs generally occur at different water depths. These results suggested that there is limited potential for sympatric speciation within these salamander populations, but the asymmetric RI might cause fitness differences between the morphs that could influence the persistence of this polymorphism.

WHITEMAN, H. H., AND R. D. SEMLITSCH. 2005. Asymmetric reproductive isolation among polymorphic salamanders. Biological Journal of the Linnean Society 86:265–281.

OBITUARIES

Herpetological Review, 2006, 37(1), 7–10.

Michael Allyn Ewert
1938–2005

DALE R. JACKSON
Florida Natural Areas Inventory, Florida State University
1018 Thomasville Road, Suite 200-C
Tallahassee, Florida 32303 USA
e-mail: djackson@fnai.org

Michael Ewert, whose work in the field of chelonian developmental biology influenced researchers around the globe, passed away from multi-focal renal cell carcinoma on 7 June 2005, at the age of 66. Until only a week earlier, extended hospice care had allowed Mike to live independently, and though his last months were uncomfortable, he managed to maintain nearly his normal schedule and concentrate on finishing projects. As a self-described loner, Mike had consciously made the decision not to seek extraordinary means to extend his life, but rather to use his remaining time to live as he always had and complete as much of his legacy of work as possible.

PHOTO BY DALE JACKSON

Mike Ewert holding a 36 kg adule male Alligator Snapping Turtle along the Apalachicola River, Florida, October 1993.

Mike learned that he had a potentially terminal disease in December 2003, but he chose to tell almost no one, so as not to cause any needless stress or concern or alter the nature of ongoing relationships. He informed my wife Ghislaine and me (with request to tell no one) in February 2005, as it had become obvious to him that it might fall on me to complete several joint papers without him (he was senior author), he expressed his desire for me to write his herpetological obituary, and he wanted my wife to have some of his artistic treasures and favorite turtles. We immediately made plans to drive to Indiana to see him; following his advice, we waited until after mid-March for winter to depart, and visited during the first week of April. The timing was fortuitous, as warm sunny weather even allowed Mike to show us two of his favorite nearby collecting localities, Griffy Lake Nature Preserve and Yellowwood State Forest, where we saw basking red-eared and painted turtles.

Mike's life was an academic one, and his work with turtle eggs led to global recognition as one of the premier developmental bi-

ologists in his field. Despite some recent forays with alligator eggs, to most of us, Mike and turtles were synonymous. In fact, turtles had been a passion since boyhood. Interestingly, though, his early scientific career focused on other taxa.

Michael Allyn Ewert was born 26 July 1938 in Cambridge, Massachusetts. He was the second of four children and the only son of Margaret Moore Ewert and Earl E. Ewert, M.D. His mother was a homemaker who enjoyed art, especially sketching and painting, and his father was a urologist at Lahey Clinic in Boston. Sister Gail (Abigail) was only two years his senior, while Barbara and Gretchen followed Mike by six and 11 years.

Young Mike developed his interests in animals early. When he was four, his family moved into a house with a backyard pool, and it was this first aquatic ecosystem that seemed to kindle the spark. He recalled at age five catching dytiscid beetles in the pool as the neatest thing he'd ever done to that time, and shortly thereafter he was chasing dragonflies with a net bought by his mother. A few wayward painted turtles picked up from the roads followed. Summer camps allowed him to further hone his skills at turtle collecting. Though he enjoyed keeping turtles, for Mike, the greatest excitement was simply in finding them.

Despite his keen mind, Mike encountered severe problems in public elementary school. Reading and writing were difficult, friends were few, and his teachers seemed just to pass him along to the next grade rather than trying to help. Although not well understood at the time, Mike suffered from the learning disability known today as dyslexia. Possibly associated with his being left-handed and possessing an artistic bent, the condition not only made learning hard but also shaped his personality. Rather than developing the assertiveness and aggression of many young boys, Mike learned to evaluate and assess situations carefully, watching rather than participating. He preferred to spend long hours alone and found it difficult to form close social bonds. However, things improved when he was taken from public school and educated for three middle grades by reading specialists at Boston University. At the same time, his mother tutored him in geography and mathematics.

From 1952–1957, Mike attended private boarding schools: first The Fessenden School, and then The Choate School, where at least a few teachers were better qualified to meet his challenge. Though he despised the first year, the schools taught him that he could succeed, and his subsequent years were more enjoyable. He gravitated toward woodshop, where he was able to express his artistic side thanks to a supportive, elderly shopkeeper. Although schedules were regimented, Mike still found time to pursue turtles. At one school set in the Connecticut countryside, he even built rock holding structures in the wooded streams, where he stashed wood turtles destined to be packed back to his Massachusetts home hidden in a suitcase of dirty laundry, along with a few spotted and box turtles.

Following high school graduation, Mike wanted to leave New England. The sight of palm trees on California's Stanford University catalog convinced him that this was where he should go for undergraduate study, and his father agreed to pay the rather low tuition at the time. Three courses taught by Paul Ehrlich, including Entomology and Evolution, were especially formative. Annual journeys from Stanford back home to Massachusetts became cross-country collecting opportunities. One highlight was the capture of a juvenile smooth softshell turtle in southeastern Colorado, a record for the state but never officially documented. He also recalled with pleasure the capture of spiny softshells in Iowa, and his amazement at the brilliant colors of his first western painted turtles, caught near Socorro, New Mexico. In 1961, Mike received his B.A. in Biology (Chemistry minor) from Stanford.

It was during his high school and undergraduate years that Mike focused on a secondary interest unknown to most of his later colleagues....art, and especially sculpture. In fact, when he entered Stanford, he had a difficult time determining whether he wanted to be a biology major or an art major. On the first evening of our visit, my wife and I were amazed as we watched him unearth many of his works from boxes, nooks, and crannies in his crowded office and even more crowded house. Wood carvings of mammals preceded a brass Chinese dragon phase, with a few paintings thrown in for good measure. Our favorite, which he bequeathed to Ghislaine for her love of softshell turtles, was a splendid rosewood *Apalone ferox*.

For graduate studies, Mike moved to the University of Minnesota. Despite his burgeoning turtle interests, the combination of his insect-chasing childhood, Ehrlich's influence, and funding opportunities funneled Mike into entomology. In 1965 he was granted an M.S. in Entomology with a Botany minor. His thesis, "Factors Affecting the Distributions of Three Species of Coccinellidae (Coleoptera) in their Microhabitat," was a carefully conducted ecological study of local ladybird beetles. It was also in 1965 that Mike married Barbara Corbett, known to many in the herpetological profession through their use of her company's (AVM Instrument Co.) radiotelemetry equipment. Although the relationship lasted little more than three years, Mike and Barbara later resumed a friendship marked by genuine mutual respect.

While working on his Master's thesis, Mike discovered that the Entomology Department had a bevy of excellent laboratory incubators. Having already found a prime painted turtle nesting area near campus, he took advantage of the situation to begin exploring the factors that determine hatchling emergence (was a cold period vital?). Despite not publishing his results, turtle eggs and their development would become his primary research focus for the next four decades.

Although remaining at Minnesota to pursue a Ph.D., a declining relationship with his thesis professor prompted Mike to leave entomology and study under Dr. John Tester, who had funding to support a field project on toads. His 1969 dissertation, "Seasonal Movements of the Toads *Bufo americanus* and *B. cognatus* in Northwestern Minnesota," yielded a Ph.D. in Wildlife Management, again with a Botany minor. While monitoring hibernating toads on wind-whipped mid-winter nights with temperatures as low as -34°C, Mike (with help from fellow graduate student Jeff Lang), managed to record some painted turtle nest temperatures as well. This stimulated him to examine super-cooling of turtle eggs and hatchlings in the lab, though equipment limitations precluded any major breakthroughs.

Upon graduation in 1969, Mike was hired to teach general zoology, ecology, and human anatomy and physiology at the University of Wisconsin Center System, West Bend Campus. He and one botanist comprised the entire Biology Department. His complete lack of prior teaching experience, coupled with an introverted personality born of dyslexia, made teaching a difficult and unreward-

ing experience, and he stayed only two years. During this time, however, he continued to capture turtles and incubate eggs. His research was facilitated by his discovery that eggs could be induced from gravid females with oxytocin (Ewert and Legler 1978), so that he could now reduce the number of turtles sacrificed and the potential impacts on small populations.

After leaving UWCS in 1971, and with no particular place to go but a desire to be in a research setting, Mike accepted the offer of his graduate school friend, Kelly Williams, to share his large abode in Bloomington, Indiana. Mike shortly established a relationship with Dr. Craig Nelson in the Biology department of Indiana University, and Craig invited him to bring his 80 turtles and share his ample lab space and conduct research there. Though surely both viewed the arrangement on a trial basis, it worked; Mike never left, and more than three decades later, he remained intimately associated with the Nelson lab. While he found formal work conducting a variety of biological field surveys through IU's School of Public and Environmental Affairs, Mike used the 1970s to develop a pioneering program in turtle embryology, much of which he summarized in two lengthy and highly acclaimed book chapters (Ewert 1979, 1985). By the early 1980s he had become especially intrigued by temperature-dependent sex determination (TSD) and was producing huge numbers of hatchling turtles for gonadal examination (a technique elucidated to him by Richard Vogt). Results were summarized in Ewert and Nelson (1991). For the next two decades, as a Postdoctoral Associate in the Department of Biology, Mike served as an inspiration, colleague, and part-time mentor to many IU students who passed through the Nelson lab.

In addition to his academic pursuits, Mike made important contributions to reptile conservation. For the past 15 years he was an active member of the Indiana Department of Natural Resource's Technical Advisory Committee for Amphibians and Reptiles. He also authored or co-authored numerous species accounts for incipient books on global turtle conservation as well as the conservation and biology of Florida turtles.

Like most herpetologists, Mike enjoyed traveling. During our interview, he recalled with joy his journeys to Mexico (in 1961 with his mother, and later for meetings and to collect turtles with John Iverson and myself), Australia (including a 1997 appointment as Distinguished Visiting Scholar at the Australian National University, Canberra), Venezuela (with Craig Nelson and son), India (with sister Gretchen to visit herpetologist R. J. Rao and the Madras Crocodile Bank), and England (1989 World Congress of Herpetology).

Mike is survived by his three sisters, Abigail Winston Ewert and Gretchen S. Ewert, both of New Mexico, Barbara Ewert Taylor, of New Hampshire, and by his good friend and ex-wife Barbara Corbett Kermeen, of Chicago Park, California..

Mike was a tireless, dedicated, and meticulous researcher who produced an extensive body of scientific research that garnered the attention of biologists worldwide. Though never in a position to direct students formally, he gave freely of his time and knowledge; upon learning of his passing, many such students as well as former colleagues shared heartfelt sentiments with me and noted the influence Mike had on their professional lives. Despite his introverted nature and often irreverent disdain for society's expectations, Mike was a truly remarkable and sensitive man. Those of us who knew him will miss his uninhibited laugh, his enthusiasm, and his presence in our lives.

ZOO VIEW

Herpetological Review, 2006, 37(1), 10–13.

Wild and Ferocious Reptiles in the Tower of London

JAMES B. MURPHY
National Zoological Park, Smithsonian Institution
Washington, DC 20008, USA
e-mail: jbmurphy2@juno.com

The Tower of London is best known as a prison where human inmates were subjected to harsh and cruel punishments so it might be surprising that this forbidding venue also served as a repository for wild animals. The Royal Collection of Wild and Ferocious Beasts kept at the Tower of London Menagerie spanned ca. 600 years, beginning in 1245 (Loisel 1912; Keeling 1992; Hahn 2004; Fig. 1). During that time, leopards, lions, tigers, ostriches, wolves, kangaroos, zebras, elephants, polar bears, monkeys, baboons, eagles and other birds of prey, macaws and other psittacines, and a stunning variety of other creatures could be found in the Tower as tourist attractions. Although seemingly not an ideal facility for reptiles with its stone walls and barred dens, at various times over the span of six centuries, the rattlesnake, the Indian boa, the anaconda, and the alligator lived in a large outdoor enclosure surrounded by a moat. All of these reptiles are illustrated in Edward Turner Bennett's book, "The Tower Menagerie: Comprising the Natural History of the Animals Contained in that Establishment, with Anecdotes of Their Characters and History. Illustrated by Portraits of Each, Taken from Life, by William Harvey, and Engraved on Wood by Branston and Wright" in 1829. Bennett described the difficulties in drawing animals, "The whole of the drawings are from the pencil of MR WILLIAM HARVEY, who, in seizing faithful and characteristics portraits of animals in restless and almost incessant motion, has succeeded in overcoming difficulties which can only be appreciated by those who have attempted similar delineations."

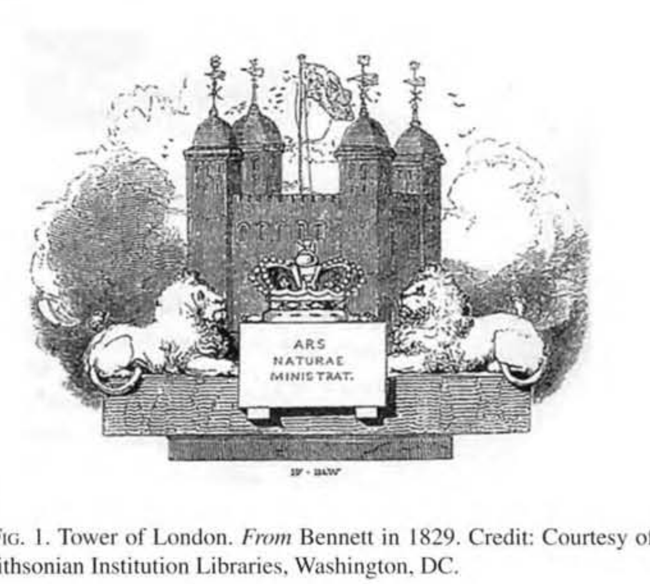

FIG. 1. Tower of London. *From* Bennett in 1829. Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

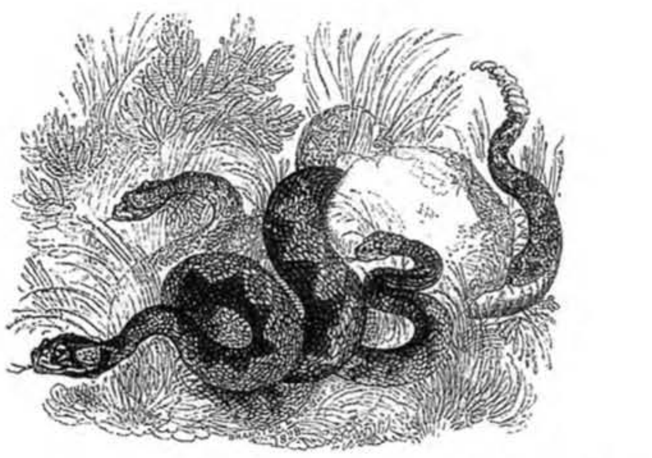

FIG. 2. Over 100 rattlesnakes (*Crotalus horridus* Linn.) lived in the Tower of London. *From* Bennett in 1829. Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

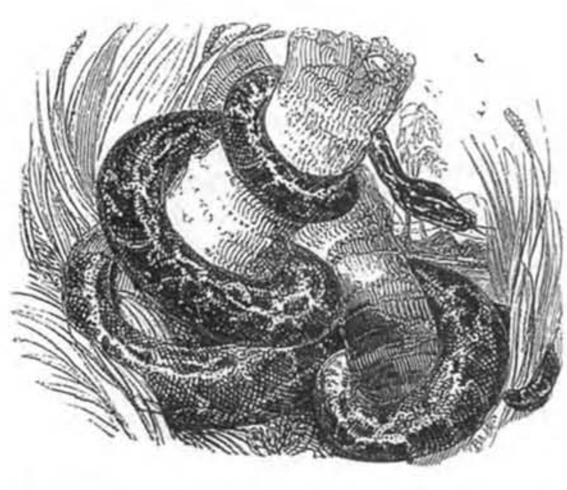

FIG. 3. Tower python, called Indian Boa (*Python Tigris* Daud., now *Python molurus*) by Bennett (1829), laid a clutch of 14–15 eggs which did not hatch. Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

Alfred Cops worked at the Exeter 'Change in the Strand but left this job in 1822 to take charge of the Royal Menagerie at the Tower. Daniel Hahn (2004) described his skills as an animal caretaker, "Cops was a professional zoologist and an expert on animal behavior, a man with extensive training and experience looking after captive animals . . . It was expected that such a man would be able to expand and improve the Menagerie, making it exciting and competitive in a way that it had not been for some years, and at the same time improve the animals' living conditions sufficiently to satisfy the newly fashionable anticruelty lobbies."

Given that rattlesnakes may be delicate to keep in captivity, it is amazing that over 100 rattlesnakes (identified *Crotalus horridus* Linn. by Bennett) survived sea voyages from the New World to be cared for by Cops in the Tower; perhaps their survival is a testament to Cops' ability (Fig. 2).

Here is Bennett on rattlesnake behavior, "It was long believed, and the notion is still popularly current, that they possessed the power of fascinating their victims, which were thought to be so completely under the influence of their glance as to precipitate themselves of their own accord into the open throat of their enemy; but the truth appears to be that they actually inspire so great a degree of terror that the animals selected for their attacks are commonly rendered incapable of offering such resistance as might otherwise be in their power, or even of attempting to escape from their pursuit."

Cops nearly bred the Tower python, called Indian Boa (*Python Tigris* Daud., now *Python molurus*) by Bennett (Fig. 3). The python laid a clutch of eggs which did not hatch. Bennett described the event, " The individual figured at the head of the present article is a female; a fact which was proved by the remarkable circumstance of her producing in May last, after having been more than two years in the Menagerie, a cluster of eggs, fourteen or fifteen in number, none of which, however, were hatched, although the mother evinced the greatest anxiety for their preservation, coiling herself around them in the form of a cone, of which her head formed the summit, and guarding them from external injury with truly maternal solicitude." This account is certainly one of the first to describe brooding behavior in pythons. Three years later, naturalist Lamarre-Picquot lectured before the Academie de France about the brooding of a *Python molurus bivittatus* in the Jardin des Plantes in Paris (Fig. 4) and claimed that the female not only coiled around the clutch but produced "noticeable warmth," a finding expressed again in a note in 1842. This observation was widely criticized as speculative, hazardous, and questionable by members of the Academie, especially Auguste Duméril (1842). The thermogenesis controversy was finally settled over 130 years later when sophisticated temperature and gas exchange recording devices were available. Victor H. Hutchison, Herndon G. Dowling, and Allen Vinegar published two important papers on metabolism, energetics and thermoregulation in brooding female pythons at the New York Zoological Society (Hutchison et al. 1966; Vinegar

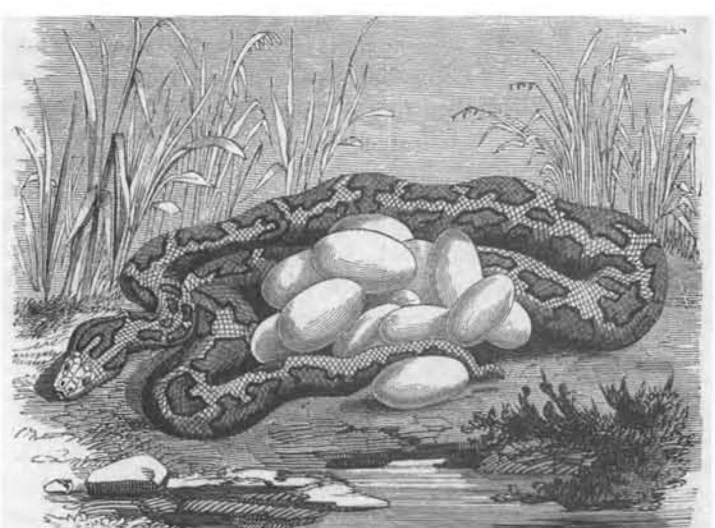

FIG. 4. Indian python (*Python molurus*) incubating eggs at Menagerie Jardin des Plantes. Illustration reproduced from S. G. Goodrich's "Johnson's Natural History, Comprehensive, Scientific, and Popular, Illustrating And Describing The Animal Kingdom With Its Wonders And Curiosities, From Man, Through All The Divisions, Classes, And Orders, To The Animalculae In A Drop of Water; Showing The Habits, Structure, And Classification Of Animals, With Their Relations To Agriculture, Manufactures, Commerce, And The Arts. Volume 2 in 1870." Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

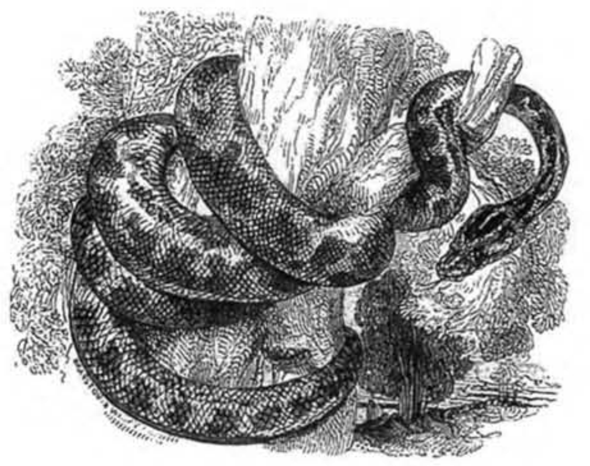

FIG. 5. The Anaconda, called *Python Tigris* Var. by Bennett, were likely Ceylonese pythons, *Python molurus pimbura*. Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

et al. 1970). The abstract in the first paper reads: "At varying environmental temperatures, measurements of body temperatures and gas exchange of a female Indian python (*Python molurus bivittatus*) show that during the brooding period this animal can regulate its body temperature by physiological means analogous to those in endotherms. Ambient temperatures below 33°C result in spasmodic contractions of the body musculature with a consequent increase in metabolism and body temperature."

The Anaconda, called *Python Tigris* Var. by Bennett, were likely Ceylonese pythons, *Python molurus pimbura* (Fig. 5). Cops discovered that captive snakes may have impressive feeding responses when one of his pythons grabbed his hand and threw two coils around his neck while being fed. Bennett told the story, "His own exertions, however, aided by those of the under keepers, at length disengaged him from his perilous situation; but so determined was the attack of the snake that it could not be compelled to relinquish its hold until two of its teeth had been broken off and left in the thumb."

Coote (2001) speculated that the first American Crocodile, *Crocodylus acutus*, received by the London Zoological Society in

FIG. 6. Tower "Alligator" called *Crocodilus lucius* Cuv. by Bennett in 1829. Note the abnormally small head. Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

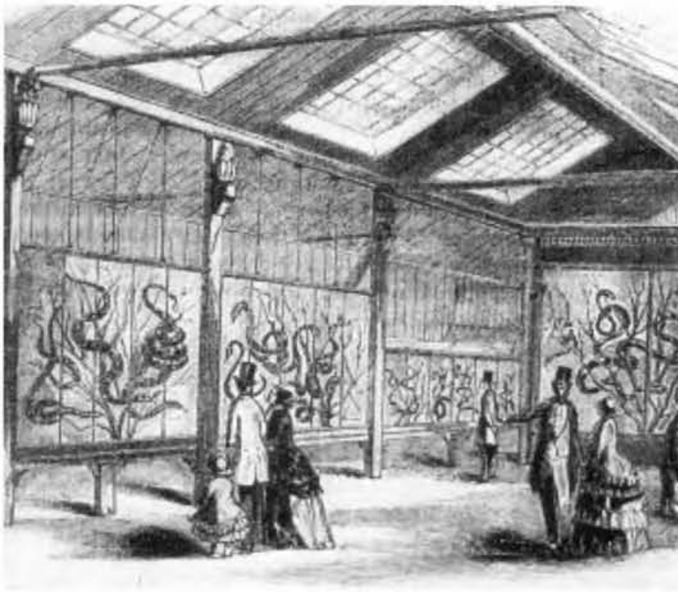

FIG. 7. Description of London Zoo reptile building from *The Illustrated London News* on 2 June 1849. The beginning of the article reads as follows: "The new reptile house in the Gardens of the Zoological Society in the Regent's Park will ultimately form one of the most instructive, as it is the most novel and original feature in this delightful institution. The collection already contained in it is so unexpectedly brilliant, considering the small number of reptiles previously exhibited in the Menagerie, that we cannot but anticipate the most important results in the study of this singularly interesting division of the animal kingdom." Credit: illustration provided by Kraig Adler.

1831, may have been the Tower "Alligator" (Fig. 6). However, the drawing by William Harvey looks like an American alligator and is called *Crocodilus lucius* Cuv., an early name for the alligator. Robert Huish's drawing in 1830 also appears to be an alligator (see Fig. 2 in *Herpetological Review* 36(3):230). In both illustrations, the alligator's head is abnormally small.

The Tower collection of animals was presented by the King to the Zoological Society of London in 1831 (Peel 1903:180). Eighteen years later, the London Zoo in Regent's Park opened the world's first zoo reptile building (Fig. 7).

Acknowledgments.—Smithsonian National Zoological Park Librarian Alvin Hutchinson, and Leslie Overstreet and Daria Wingreen in the Joseph F. Cullman 3rd Library of Natural History (from the SI Special Collections Department) helped locate historical literature. Judith Block and Jon Coote reviewed early drafts of this manuscript. I thank Kraig Adler for providing the illustration of the reptile building at London Zoo.

This contribution is dedicated to Jon Coote, who has expanded our understanding and appreciation of early herpetocultural practices through his writings.

Reproduction and Growth of Seven Species of Dwarf Geckos, *Sphaerodactylus* (Gekkonidae), in Captivity

RUBÉN REGALADO
4841 West 3rd Avenue
Hialeah, Florida 33012, USA
e-mail: regalado05@bellsouth.net

A diversity of reproductive, growth, and survival strategies (Shine and Charnov 1992) have made lizards model organisms in the investigation of how environmental factors and phylogenetic constraints shape life-history traits (Clobert et al. 1998; Dunham 1978; Shine and Greer 1991; Sinervo and Adolph 1994; Tinkle et al. 1970). However, ecological studies on the family Gekkonidae, the second most speciose family of lizards (Uetz 2000), are few (see Vences et al. 2004 and references therein). Small and usually invariant clutch sizes (Kluge 1987, but see Colli et al. 2003; Shine and Greer 1991), nocturnal activity, and microhabitats that are usually not conducive for easy field observation and manipulation may have biased researchers against selecting geckos for life-history study. The lack of life history information is even more evident in dwarf geckos, genus *Sphaerodactylus* (Krysko et al. 2003; López-Ortiz and Lewis 2002). However, some dwarf gecko species are believed to reach the highest known population densities of terrestrial vertebrates in some areas (Rodda et al. 2001). Miniaturization in *Sphaerodactylus* has led to even more secretive habits and, thus, amplified the problems of tractability.

Because most *Sphaerodactylus* species are typically parapatrically distributed, are similar in shape, and published descriptions of their microhabitat are usually general, they have been assumed to be ecologically similar (but see Thomas et al. 1992). Still there may be important differences in ecological factors that have been overlooked. For instance, selection acting on a gecko that inhabits and defends the underside of a rock should be different from those acting on a congeneric inhabiting the adjacent leaf litter; likely, they would face different predators, hunt different prey, and experience different social environments, but have been reported simply as living in the leaf litter.

The major objective of this study is to describe reproduction and growth in seven *Sphaerodactylus* species kept in captivity. Although data from captive populations may be different from wild populations (e.g., growth rates/clutch sizes may vary in relation to proximate climate factors and food availability [Stamps and Tanaka 1981]), they may be useful for uncovering differences among related species that could generate testable hypotheses, suggest field research projects, and help interpret field data.

Sphaerodactylus nicholsi, *S. townsendi*, and *S. roosevelti* were collected from backyards and dumpsites on the southwestern coast of Puerto Rico (Guanica, Ensenada, Punta Verracos, Punta Pestillo, Paso Seco, and Salinas) in 1995, 1997, and 1999. Individuals of *S. nigropunctatus granti*, *S. argus*, and *S. pimienta* were obtained from eggs collected in eastern Cuba (Holguín, Belic, and El Yarey, respectively). *S. savagei* adults, from the northeastern of Dominican Republic, were obtained from a South Florida dealer in 2001. The natural history for most of these species is summarized by Schwartz and Henderson (1991). Nothing is known about the natural history of *S. pimienta*.

Lizards were housed individually or in male-female pairs in plastic containers (1.9 L), kept indoors, and were exposed to natural light cycles (through open windows) typical of South Florida. Containers were provided with a substrate made of soil and peat moss, a few small rocks, dead leaves and pine bark. Enclosures were misted with water three times a week and exposed to daily and seasonal temperature and humidity changes. Mean air temperature ranged from 24°C to 33°C from April through October and from 14°C to 23°C from November through March, from 1996 to 2001. Vitamin and mineral-dusted insect larvae and adults (fruit flies, humpback flies, crickets, and ants) were provided at two or three day intervals.

Containers were inspected weekly to find newly laid eggs, usually under leaves, bark, or in the substrate 1–2 cm below the surface. The largest and smallest egg diameters were measured to the nearest 0.1 mm with an ocular micrometer. Eggs were placed individually in small plastic containers (30 cc) with a sterile soil/peat moss substrate and incubated in a plastic box (20 x 20 x 30 cm) in the same room, exposed to daily and seasonal temperature fluctuations. Eggs were checked every week during the first month of incubation, and later in the study every day. To explore the potential effect of temperature on incubation duration (Andrews 2004), individual records for each species were pooled into two groups: eggs incubated during May–October (high temperature)

and eggs incubated during the Nov–April (low temperature). Incubation duration and snout-vent length (SVL) of neonates, measured to the nearest 1 mm with a plastic ruler, were recorded. For females that survived at least until November in a year, I estimated oviposition frequency (days) and annual egg production.

Snout–vent length of all individuals was measured monthly, but also when I noticed the first sign of sexual maturity: the escutcheon, a triangular group of discolored scales on the posterior abdominal region of males, and the first oviductal egg in females. Four of the taxa (*S. nicholsi*, S. *n. granti*, *S. savegei*, and *S. roosevelti*) exhibit sexual dichromatism, all or some males develop a different color pattern than females. As the change in male coloration started several weeks after the emergence of the escutcheon, SVL was also recorded at this time. Finally, a sexual size dimorphism index (SDI) for each species was calculated following Lovich and Gibbons (1992) as: (mean asymptotic size of females/mean asymptotic size of males) - 1. Asymptotic size (Stamps and Andrews 1992) was estimated as the SVL of individuals that survived at least six months in captivity and did not grow during this period.

Growth characteristics were described by fitting data from captive-born individuals using the logistic-by-length model (Schoener and Schoener 1978), $L = a/(1 + be^{-kt})$, where L is the SVL at time t (in months), a is the maximum (asymptotic) length, e is the base of natural logarithm, k is the intrinsic growth rate or rate of approach to a, and b is related to hatchling size. Data for each gender were analyzed separately using CurveExpert (Hyams 2003). To explore the influence of temperature on growth rate, monthly relative growth rate was calculated for all individuals as the difference in SVL between two measurements divided by the SVL at the first measurement.

Mean, standard deviation, range, and sample size for each trait are presented in Tables (1–3), but medians are compared in box plots when extreme outliers are present. Pearson's correlation coefficient (r) was estimated to show the relationship between variables. No statistical test was performed to compare those statistics between genders or species because of the small sample sizes.

Relationships between egg traits and female and hatchling SVL were similar to other geckos (Vitt 1986). For example, the mean egg diameters and offspring size covaried at species level with mean asymptotic size of females (Tables 1, 2; Fig. 1A, B, C). Also, no intraspecific correlation between egg size or hatchling SVL and female SVL was found in any species (Okada et al. 2002). However, as annual egg production was usually higher in the second year of life when most females reached their asymptotic size (Table 1), annual egg production may be positively related to female SVL. Moreover, some females in four species (*S. nicholsi*, *S. argus*, *S. roosevelti*, and S. *pimienta*) oviposited fertile eggs after spending six or more months alone, illustrating the potential for sperm storage suggested for other geckos (Bou-Resli et al. 1981).

The oviposition frequency varied within and among species (Table 1), and its median seemed related to species asymptotic size: approx. 20 days among the smallest species and 30 days in the medium to largest species (Fig. 1D). Most species concentrated their reproductive output in the warmer and more humid months of the year, but *S. argus* laid eggs almost continuously throughout the year (Fig. 2A). In all species, periods of almost continuous egg-laying activity were interspersed with resting periods of different duration. *Sphaerodactylus* may be capital breeders like many lizards (Bonnet et al. 1998), but the energy, proteins, and calcium stored in their small bodies might not sustain their annual egg production and, thus, might require rest periods to replenish energy and nutrient reserves to continue laying eggs.

All species had the typical clutch size of the genus (Kluge 1987), i.e., one egg. However, a few females of *S. nicholsi*, *S. argus*, and *S. nigropunctatus* occasionally showed two large-shelled eggs, al-

TABLE 1. Female egg and incubation data for seven species of *Sphaerodactylus*. Mean ± SE (range; N).

Species	Egg diameters (mm)		Annual egg production		Oviposition frequency (days)	Incubation duration (days)
	Largest	Smallest	1st yr of life	2nd yr of life		
S. nicholsi	5.3 ± 0.1 (4.9–6.1; 8)	4.3 ± 0.1 (3.9–4.9; 8)	8.6 ± 0.7 (6–12; 9)	11.8 ± 2.4 (5–16; 4)	19.5 ± 0.7 (10–50; 17)	62.5 ± 2.4 (53–78; 26)
S. townsendi	5.9 ± 0.1 (5.4–6.2; 7)	4.3 ± 0.2 (3.3–4.8; 7)	5.3 ± 0.9 (4–7; 3)		19.4 ± 1.1 (13–33; 8)	76.6 ± 10.2 (58–93; 3)
S. argus	7.2 ± 0.1 (6.9–7.5; 7)	5.4 ± 0.0 (5.1–5.6; 7)	6.8 ± 1.6 (4–12; 5)		29.3 ± 2.6 (10–60; 6)	64.0 ± 2.0 (53–80; 15)

S. n. granti	7.4 ± 0.1 (7–8.1; 1)	5.8 ± 0.1 (5.4–6.2; 1)	3.0 (1)	9.0 (1)	22.2 ± 3.6 (11–59; 2)	81.0 ± 6.4 (74–94; 3)
S. roosevelti	8.6 ± 0.1 (8.5–8.6; 2)	6.2 ± 0.2 (6–6.4; 2)	5.0 (1)	5.0 (1)	26.8 ± 2.3 (21–31; 4)	67.0 ± 13.0 (54–80; 2)
S. pimienta	9.1 ± 0.1 (8.6–9.6; 9)	7.0 ± 0.1 (6.6–7.4; 9)	2.8 ± 0.3 (2–4; 6)	5.7 ± 0.9 (4–7; 3)	45.0 ± 5.6 (17–121; 7)	76.3 ± 4.1 (53–125; 20)

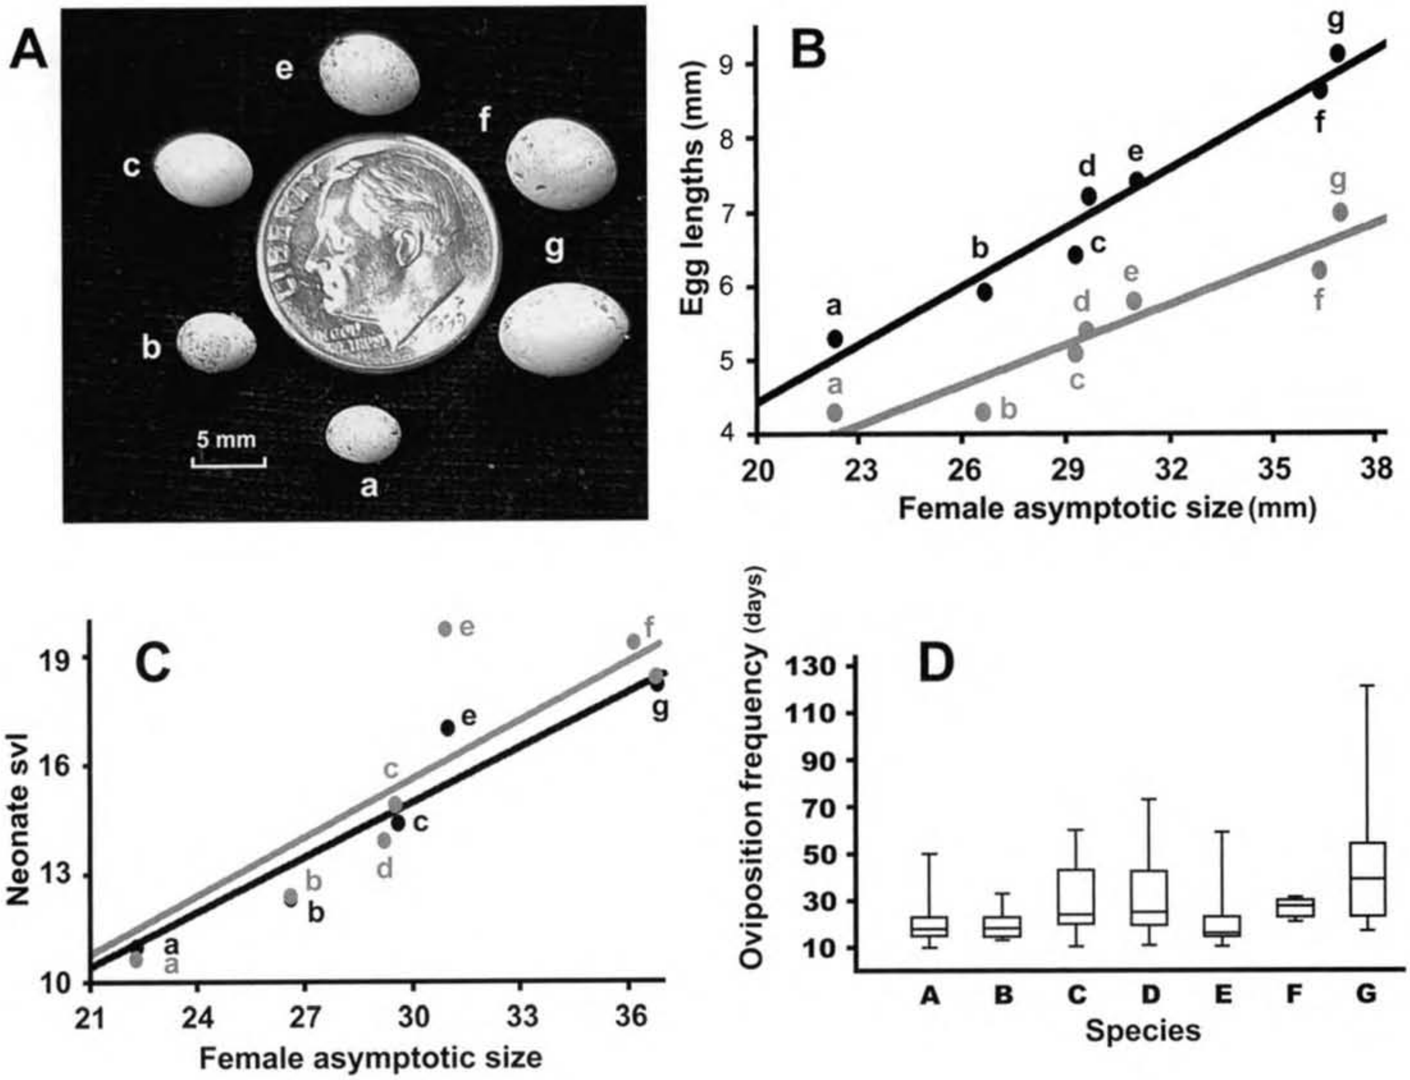

Fig. 1. A: Eggs of six species of *Sphaerodactylus*; a = *S. nicholsi*, b = *S. townsendi*, c = *S. argus*, e = *S. nigropunctatus granti*, f = *S. roosevelti*, g = *S. pimienta*. B: Interspecific relationship between female asymptotic size and egg diameters (black = largest, r = 0.9; gray = smallest, r = 0.9); all symbols as in Fig. 1A, except d = *S. savagei*. C: Interspecific relationship between female asymptotic size and neonate size (black = male, r = 0.9; gray = female, r = 0.8); all symbols as in Fig. 1B. D: Interspecific variation of oviposition frequency (days). The 25th and 75th percentiles are drawn using a box. Median is shown with a horizontal line inside the box. Minimum and maximum values are shown with vertical lines, all symbols as in Fig. 1B.

most in the same stage (Fig. 2B). Beebe (cited by Fitch 1970) found a wild female *S. molei* that also had two eggs ready to be oviposited. Also, L.M. Díaz (pers. comm.) observed a female *S. nigropunctatus lissodesmus* laying two eggs sequentially and manipulating them with the hind limbs (Fig. 2C). Hence, it appears that females in some *Sphaerodactylus* species have the ability to synchronize the activities of both ovaries which may increase annual egg production, perhaps when environmental conditions are most favorable.

The mean egg incubation duration was highly variable within and among species (Table 1), and it did not seem correlated to female asymptotic size. As expected, incubation duration was affected by air temperature. In the warmer months, most eggs hatched in about two months, but incubation could last up to four months in the colder months (Fig. 2D).

Growth patterns were similar to other lizards (Andrews 1982), including geckos (Kratochvíl and Frynta 2003; Okada et al. 2002), i.e., both genders matured at a small size and continued growing asymptotically (Fig. 3; Tables 2, 3). Intrinsic growth rates showed no intergender difference and seemed to be inversely correlated with neonate and asymptotic size. Sexual size dimorphism was only appreciable in *S. nicholsi* and *S. townsendi* (Table 2) and was the result of postmaturational events (i.e., both genders grew similarly until maturation started, afterwards, females grew at faster rates than males, Fig. 3). Whereas the slow growth rates in *S. argus* were an expected artifact because several individuals hatched in the winter months, the slow growth rates in *S. nigropunctatus* (km = kf = 0.17) could be the result of inbreeding depression (Lacy et al. 1993). Low fecundity and survival were evident in most young individuals after three or four generations, but were more prominent in *S. n. granti*.

Furthermore, relative growth rates were highly influenced by temperature (Fig. 4A, B). Typically, whereas individuals born during the summer showed fast relative growth rates during the first

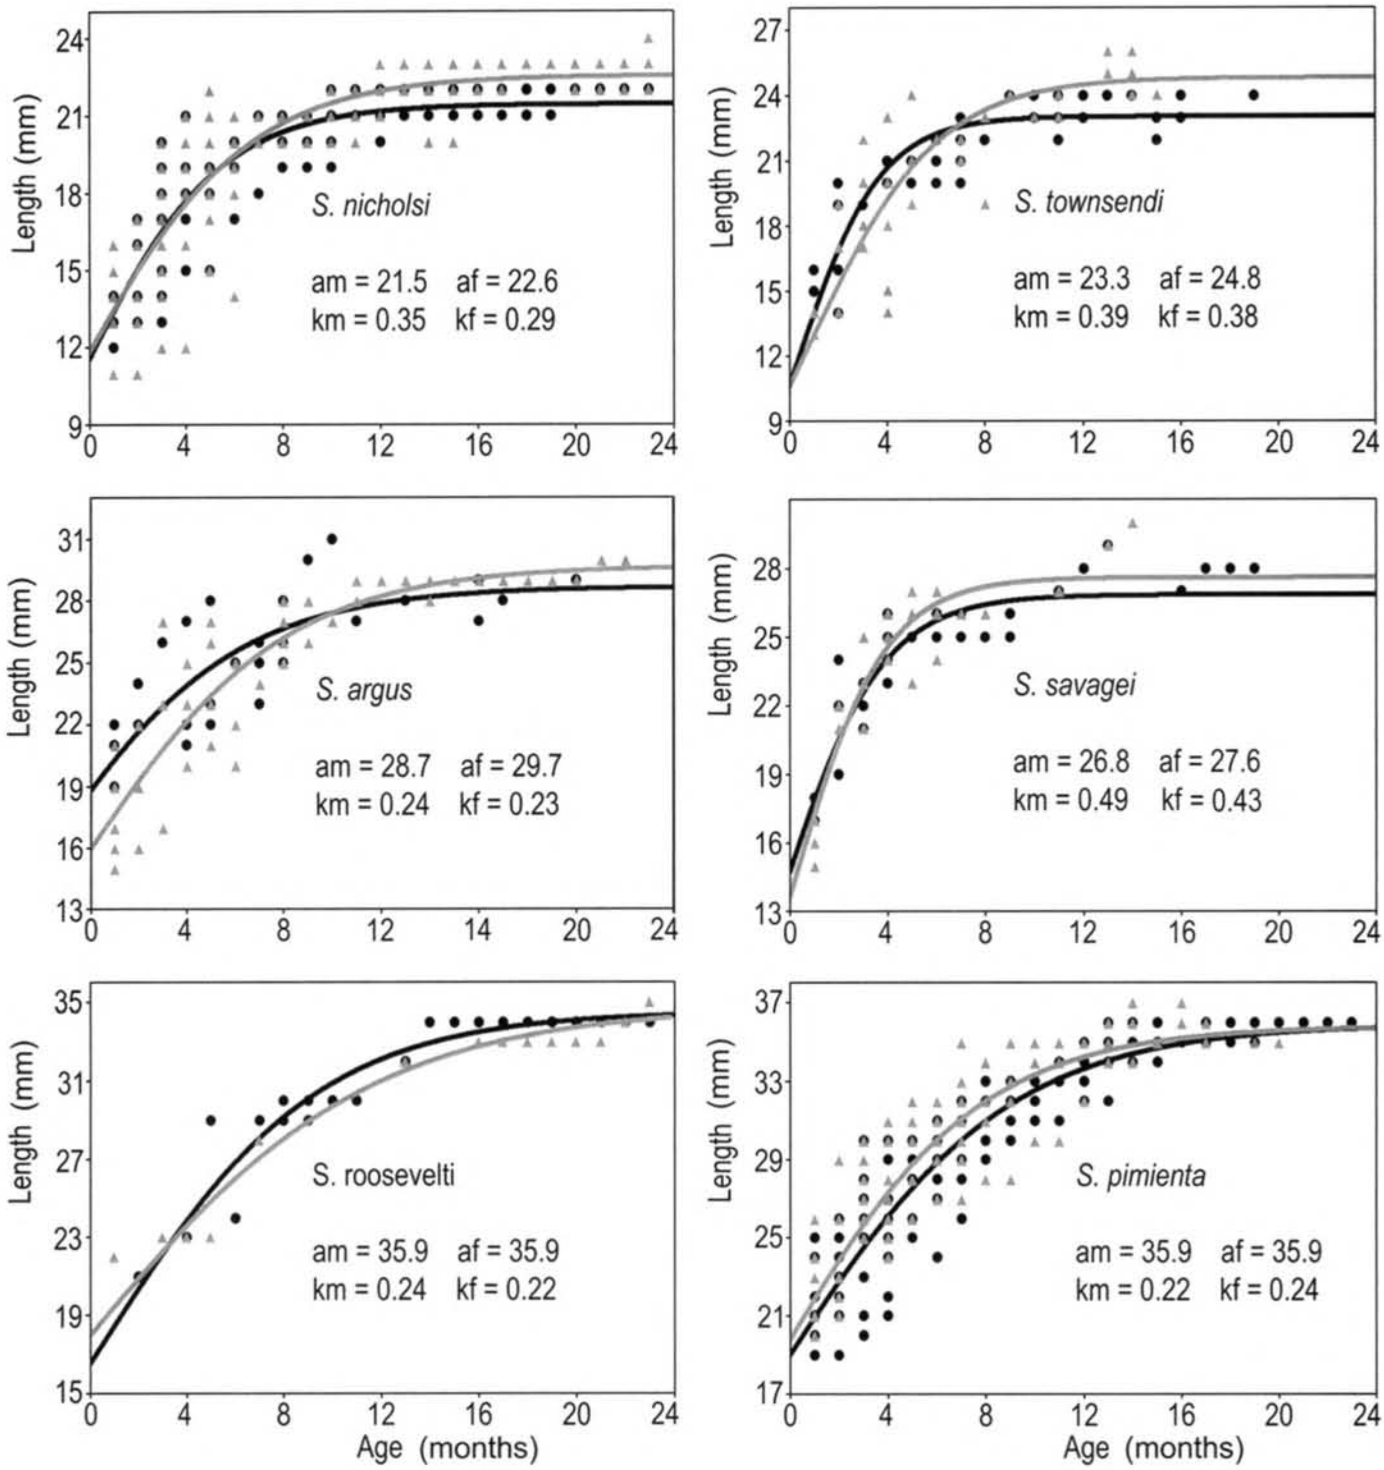

FIG. 3. Changes in SVL of seven *Sphaerodactylus* species during the two first years of life. Dark dots represent males, gray triangles females. *S. nicholsi*, N = 18/29 (males/females); *S. townsendi*, N = 7/11; *S. argus*, N = 6/9; *S. savagei*, N = 5/5; *S. roosevelti*, N = 2/2; *S. pimienta*, N = 15/12. am/af and km/kf represent the maximum length and the intrinsic growth rate for males and females, respectively, estimated from the logistic-by-length model.

three or four months of life; individuals born during the winter practically did not grow during the same period. However, these individuals showed a capability to catch up by growing at relatively fast growth rates later.

Although male and female SVL were similar at hatching (Table 2), males of all species showed a sign of maturation onset (i.e., escutcheon development) before females. However, the size of the escutcheon increases with age (Menchel and Maderson 1975). For example, the escutcheon of *S. nicholsi* and *S. pimienta* first appeared as a small triangular area, but it reached the invariant adult size, which extends onto the thighs (Fig. 4D), in about 2 to 3 weeks and 2 to 4 months, respectively. Thus, using the onset of

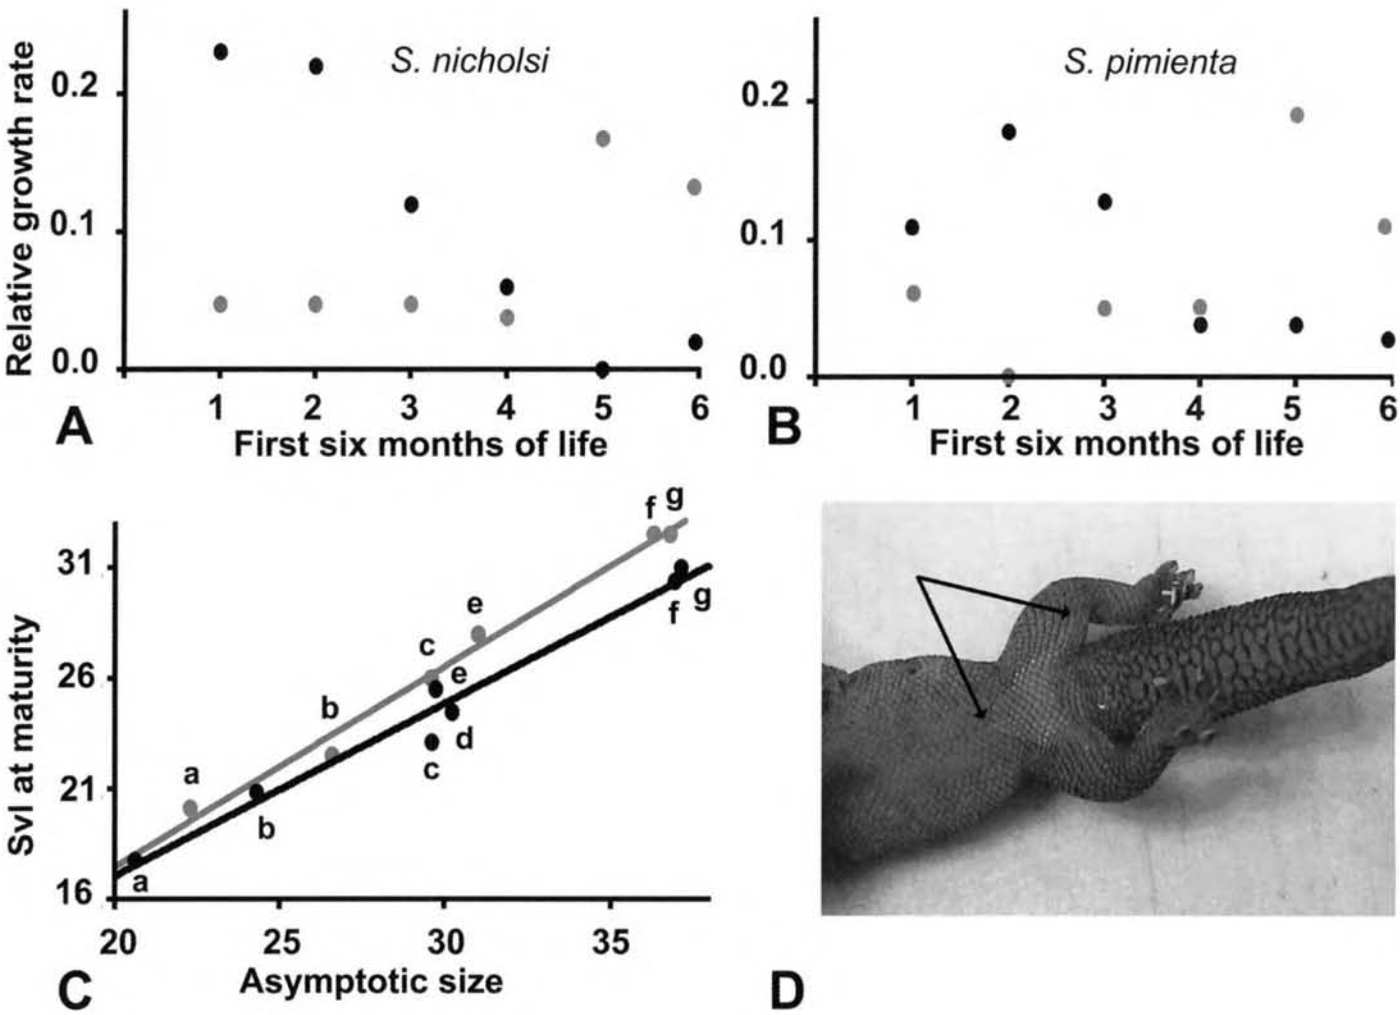

FIG. 4. A, B: Effect of temperature on relative growth rate for two species of *Sphaerodactylus*. Black dots stand for the average relative growth rate of individuals hatched in May–October during their first six months of life; gray dots for individuals hatched in November–April. C: Interspecific relationship between size at maturity and asymptotic size; black for males (r = 0.9), gray for females (r = 0.9); all symbols as in Fig. 1B. D: Escutcheon of an adult male *S. pimienta* extends onto the thighs.

escutcheon development to estimate the age and SVL at maturity in males may underestimate both statistics. Besides, the onset of escutcheon development does not necessarily indicate young males are capable of successful mating and reproduction. Even though I found that escutcheon development coincided with the onset of male-specific courtship displays, young males may not compete successfully with other males for territories or receptive females or may be physiologically unable to produce viable sperm. A lag between the onset of the escutcheon and the onset of male specific color patterns in dimorphic species (Table 3) supports this hypothesis. Furthermore, given that the sign of female maturation probably appeared one or two weeks after the first ovary cycle and that change of male pattern started at almost the same age of the first oviductal egg (Table 3), both genders may mature at the same time.

As expected (Stamps et al. 1998), size and age at maturity were positively correlated with asymptotic size among species (Tables 2, 3; Fig. 4C). Whereas *S. nicholsi* and *S. townsendi* were mature and started reproducing after their fifth or sixth month of life, it took a year to start reproduction in *S. roosevelti* and *S. pimienta*. Moreover, usually the first clutches of these last two species had high oviposition frequencies and usually failed to hatch.

Longevity of most individuals in all species commonly exceeded two years, and living more than four years was frequent in *S. nicholsi*, S. *argus*, S. *savagei*, S. *n. granti*, and *S. pimienta*. Decreased longevity in *S. townsendi* and *S. roosevelti* was probably the result of a diminished adaptation to captivity instead of innate species-specific differences. Colonies of these latter two species never thrived like the other species. Given that the maximum SVL recorded for wild-caught individuals in all species (see Schwartz and Henderson 1991) is similar or usually higher than the asymptotic sizes found in this study, it seems likely that the lifespan of some individuals in the wild may extend beyond a year in the five small species and two years in *S. roosevelti* and *S. pimienta*.

Information obtained on reproduction and growth of captive *Sphaerodactylus* may be useful in explaining data from field studies. For instance, López-Ortiz and Lewis (2001) reported the presence of gravid females and hatchlings in all months in a wild population of *S. nicholsi*, which agrees with my observations, and attributed a lag between the peak abundances of both stages (gravid

Table 3. Age at Different Stages of Seven Species of *Sphaerodactylus*. Mean ± SE (range; N). Age is in months.

Species	Age at first escutcheon	Male age at pattern change	Female age at first oviductal egg	Male age at asymptotic SVL	Female age at asymptotic SVL
S. nicholsi	5.8 ± 0.5 (4–8; 10)	8.5 ± 1.6 (6–13; 4)	8.4 ± 0.5 (6–10; 9)	16 ± 2.8 (6–24; 6)	18.8 ± 2.6 (6–32; 9)
S. townsendi	5.8 ± 0.4 (5–7; 6)			13.5 ± 0.8 (11–16; 6)	13.3 ± 0.7 (12–14; 5)
S. argus	4.6 ± 0.8 (3–7; 5)		8.8 ± 0.7 (6–10; 6)	13.3 ± 4.1 (7–21; 3)	18 ± 1.8 (12–25; 6)
S. n. granti	4.7 ± 0.3 (4–5; 3)	7.7 ± 0.9 (6–9; 3)	8.0 (3)	19.7 ± 4.3 (14–28; 3)	37.0 (1)
S. roosevelti	7.5 ± 2.5 (5–10; 2)	16.5 ± 1.5 (15–18; 2)	19.5 ± 0.5 (19–20; 2)	28.0 (1)	24.0 (1)
S. pimienta	8.1 ± 0.5 (5–11; 14)		10.3 ± 0.6 (8–12; 6)	33.3 ± 1.9 (25–37; 7)	26.8 ± 3.4 (16–46; 8)

females in July and hatchlings in January) to incubation durations two times greater than the ones I recorded for this species. However, a relatively larger number of hatchlings would also be expected after a few months in recently founded populations. In a small population founded during the spring by a few individuals, early maturation, allowing two generations a year, coupled with a shorter incubation time and fast growth rates would result in an increasing number of reproductive adults by late summer or early fall. Considerable egg laying could continue through early November and could result in a population of eggs that start hatching in December and January, swamping the population with neonates. Alternatively, life-history traits of the population studied by López-Ortiz and Lewis (2001) could be different from the one described here; indeed, some evidence of morphological and behavioral differences has been recorded (Regalado unpublished). Another difference between findings of our studies relates to neonate size. As the asymptotic size of *S. nicholsi* from Cabo Rojo is higher than the asymptotic size of *S. nicholsi* from Guanica, the extremely low values found for neonate and gravid female SVL in the first population are not expected and are difficult to explain.

Some differences in asymptotic sizes between this study and literature records may be accounted for by interpopulation variation and biased age distribution of small samples. For instance, asymptotic size in *S. n. granti* was around 30 mm, whereas Schwartz and Henderson (1991) reported a maximum SVL of 40 mm for *S. nigropunctatus*. The discrepancy between both estimates arises because Schwartz and Henderson's comprehensive review includes *S. n. ocujal*, which individuals are much larger. Furthermore, maximum sizes reported for males and females of *S. pimienta* (Thomas et al. 1998) are lower than the asymptotic sizes I recorded. The escutcheon size and the SVL of the only male these authors described indicate it was young, probably less than a year old. However, although the eggs used to start my *S. pimienta* colony came from a site only 21 km away from the population described by Thomas et al. (1998), there is a color difference between individuals from both populations, dark gray in El Yarey and tan in La Pimienta.

The high variation in oviposition frequency and incubation duration, as well as a small variation in clutch size, suggest two caveats for field studies. First, estimates of incubation duration of eggs found in the wild may be inaccurate. Second, the proposition that in *Sphaerodactylus*, and other species with a minimum clutch size, nests with a small number of eggs represent intraspecific communal nesting (Oda 2004) may also be invalid. One female could possibly lay 5 or 6 eggs in two months before the first egg laid completed incubation and hatched.

This study suggests that considerable interspecific variation exists in the life-history traits of captive *Sphaerodactylus* that could reflect adaptive species differences. All seven species studied here seem to follow typical lizard life histories: growth rates decline with age; age at maturity and survival covary positively, and both parameters covary negatively with fecundity (Clobert et al. 1998; Shine and Charnov 1992). Consequently, *Sphaerodactylus* species may range along a gradient of small, early-maturing, high-fecundity, and short-lifespan species to relatively large, late-maturing, low-fecundity, and longer-lifespan species.

Acknowledgments.—I thank A. Pérez-Asso, A. Silva, and L. González for their assistance with field work in Puerto Rico, V. González for logistic support, and L. M. Díaz for donating the eggs of Cuban *Sphaerodactylus*, sharing information on *Sphaerodactylus* species, and giving permission to use his artwork. K. L. Krysko, C. K. Dodd, and S. A. Johnson made invaluable comments that greatly improved the manuscript.

Chamaeleo montium is a medium sized arboreal chameleon found in southwestern Cameroon at elevations of 500–1200 m (Hofer et al. 2003; Mertens 1938). It is reported from forest, gallery forest, hill forest, and farm bush (Klaver and Böhme 1986; Lawson 1993). This species is early maturing and reproduces continuously with an approximately two-month gestation period. The majority of the behavioral information known regarding this species is from observations of captive individuals. The few in situ studies found in the literature expound upon its diet and elevational range (Hofer et al. 2003), individual perch height (Harbort and Herrmann 2002; Lawson 1993), or reproduction (Herrmann and Herrmann 2005; Herrmann and Solèr-Kühni 2005). Studies involving movements or territory investigations are entirely lacking. Here we report on movements involving six chameleons (3 males, 3 females) which we observed for up to twenty-week periods. These observations detail microhabitat usage and provide the first insight into home range and territory.

The study site was a 30 x 37 m cultivated garden adjacent to secondary forest and farm bush in the village of Nyasoso (4°49' 289"N, 9°40'826"E; elev. 850 m), at Mt. Kupe, Southwest Province, Cameroon. Buildings included two large two-story houses, encircled and connected by verandas on the second floor which facilitated the observations of chameleons when they were up in trees. Additional structures were small or limited to trellises for vines; plants were numerous, including several trees. The grass interspaces were kept cut uniformly short. The structure and canopy provided here is less than what a forest or farmbush habitat would usually provide, however, this species is commonly found in very open habitat (pers. obs.).

The study period comprised mid-November 2002 to the beginning of April 2003 which encompasses all of the dry season. For

climatic data for this period see Herrmann and Herrmann (2005).

We caught 20 chameleons and individually marked them with nail polish during the 20-week study period. The nail polish color was shed upon ecdysis, however, subsequent epithelial layers were stained by the polish leaving a 'water mark' which was easily read, allowing for the chameleons to then be repainted. Three mature female and three mature male chameleons were sighted repeatedly and allowed for a detailed study of their behavior. The remaining 14 chameleons were sighted only a few times before disappearing for long periods of time, or disappearing altogether from the study area and thus are not considered in this report. No juvenile chameleons < 6 cm snout–vent length were encountered.

We opportunistically conducted focal observations during day and night. Chameleons found interacting or in the vicinity of other chameleons were checked repeatedly throughout the day. We recorded the location of the chameleons using a two-dimensional map, thus all distances are aerial straight-line distances and do not take the measurement of height (i.e., trees) into consideration; this often significantly underestimates the actual distance traveled by a chameleon. Straight-line distances were measured from tree trunk to tree trunk in the case of isolated trees where a crossing via canopy was not possible. The chameleons appeared to be unaffected by our presence.

We observed three female chameleons (#'s 01–03), two for 20-week periods, the third for a 51-day period. Two of the females were quite sessile for the period observed, while the third ranged broadly (Fig. 1). We observed Female #01 for 20 weeks, beginning 16 November, during which she was courted and mated two times by a male (#06) (see Herrmann and Solèr-Kühni 2005). The female inhabited a 4 x 5 m area, consisting of a large bush (*Penianthus* sp.) and a guava tree (*Psidium* sp.), which was bordered on one side by the larger house. The only departure from this area involved a one-week venture at which point she crossed ca. 10.5 m of open grass to reside in a small, isolated apple bush (*Eugenia* sp.). At this time she was gravid, presumably from the 10 November mating with Male #06, but was being courted, unsuccessfully, by a male (#04) which had recently taken up residence in her original bush ca. one week prior to the female's departure. This female was observed dark in color and chasing the male away a few days prior to her move. It is possible that his presence influenced her leaving. One week after taking up residence in the apple bush, the female returned to her original bush. Although the male (#04) was still in the vicinity, further interactions were not observed. In summary, 95% of the 20-week period for this female (#01) was spent in the 4 x 5 m area. For detailed reproductive behavior involving this female see Herrmann and Solèr-Kühni (2005).

We observed a second female (#02) for 51 consecutive days, beginning 25 November, which also showed high site fidelity. Her appearance and departure at the site, which required a series of 2-m crossings of open grass, were abrupt. However, for the time period during which she remained at the site her activities were confined to a 2 x 3 m area of passion fruit vine (*Passiflora* sp.) which was located adjacent to the larger house. This female was never observed interacting with any other chameleons, although at mid-stay an additional female (#03) also utilized the vine area for ca. one week. Female #02 was never relocated post departure.

The scenario presented by Female #03, which we observed for a 20-week period, beginning 16 November, provides an opposite extreme to the previous. This female executed her activities within a 20 x 30 m plot, navigating several human structures and crossing up to 6-m expanses of open grass repeatedly. Her movements followed a somewhat circuitous route involving four primary locations. The first location was the 2 x 6 m crown of a leukazia tree (*Leucaena* sp.), adjacent to the smaller house, where she spent 25% (five consecutive weeks) of the study period. The second location was in the 4.5 x 3.5 m canopy of a leukazia tree where she then remained 5% of the study period (one week) with the exception of two days mid week during which she was found again at location one. This female then traveled ca. 20 m to a third location, the passion fruit vine growth adjacent to the larger house where Female #02 was in residence. No interactions were observed between the two females. At this time Female #03 could be observed at close range and appeared to be very gravid. However, we did not abdominally palpate to confirm this observation. Female #03 then spent ca. 15% (ca. three weeks) of the study period in this 3 x 8 m area. Because of the protected, brushy nature of this site and the advanced gravid state of Female #03, it is possible that egg deposition occurred during this time. An unknown male was observed one day near this female, but no interactions were observed.

Female #03 was next found at location two where she then spent ca. three weeks before we found her in another leukazia tree, location four. Access to this site entailed a travel of 20 m and required crossing open areas of grass; this distance was traversed in one afternoon. By evening this female was found attended by an unknown male which remained near her for three days. After ca. one

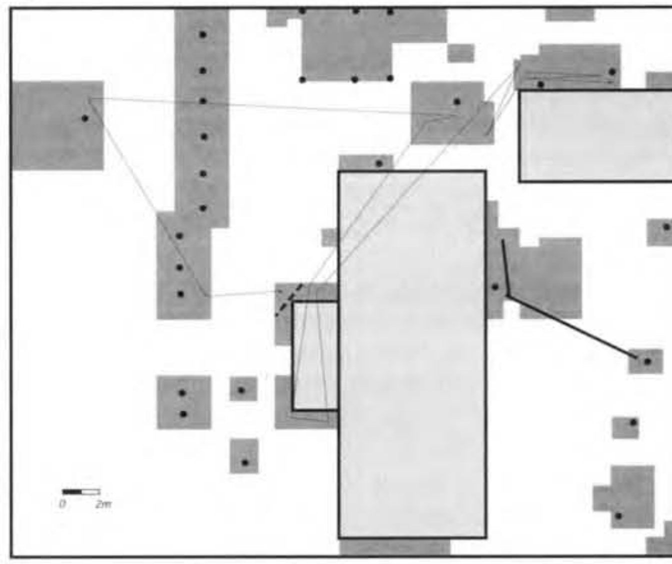

Fig. 1. Map of the 30 x 37 m study area and female chameleon movement lines. Dark gray areas indicate approximate foliage canopy area. Black dots indicate tree trunks whereby chameleons must ascend trunk (dot) to access canopy habitat. White areas indicate open grass or other nonhabitat areas. Light gray areas indicate the two houses; chameleon movement lines which cross these areas indicate the direction of and not the actual movement path of the chameleons which had to circumnavigate these structures. Female #1 is represented by the broad solid line. Female #2 is represented by the thin solid line with an arrow to show direction of movement. Female #3 is represented by the dashed line.

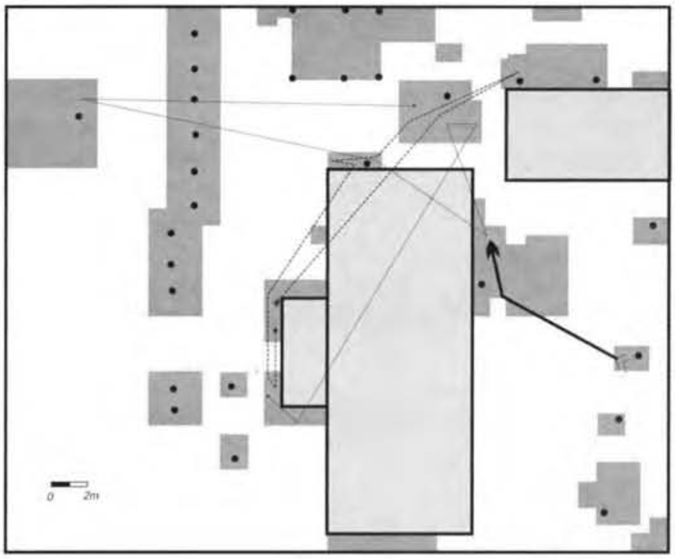

FIG. 2. Map of the 30 x 37 m study area and male chameleon movement lines. Dark gray areas indicate approximate foliage canopy area. Black dots indicate tree trunks whereby chameleons must ascend trunk (dot) to access canopy habitat. White areas indicate open grass or other nonhabitat areas. Light gray areas indicate the two houses; chameleon movement lines which cross these areas indicate the direction of and not the actual movement path of the chameleons which had to circumnavigate these structures. Male #1 is represented by the dark broad line. Male #2 is represented by the broad broken line. Male #3 is represented by the thin solid line. Arrows indicate movement direction.

week at this location, this female was not found for four weeks, representing 20% of the 20-week study period. Most likely the female had moved beyond the boundaries of the study plot. She was later discovered once again at location three where she stayed for the remaining three weeks of the study period.

In contrary to these females, the males (#04–06) represent a rather uniform group. We observed the males over a time period ranging from 31 to 35 days during which their sole objective appeared to be locating and pursuing females.

Male #04 was first found in a small isolated apple bush and then observed for 31 days consecutively (Fig. 2), beginning 31 December. This chameleon was dramatically disfigured, apparently by a native's machete. Both its front and hind legs were cleaved off on the right side of its body and the right horn was severely attenuated. The healed scarring ruled out birth deformities. Nonetheless, this animal was large, robust, and after a two-day pause, successfully crossed the 10.5 m exposed grass expanse to the bush/tree location of Female #01. This male spent 29 days in a 2 x 5 m area alternately attempting courtship, unsuccessfully, with Female #01, which was gravid at the time. After this, this male was not found again.

We observed Male #05 for a period of 35 days, beginning 16 November, during which this male transversed 13 m along the shrubbery of the house, then followed a 19 m trajectory which involved climbing three trees, requiring descents and crossings of open ground of six and five meters. This chameleon was most often observed moving, appearing to systematically search vegetation. He slept in a different location every night. The only time we observed this male to be sessile was during his attendance of an unknown female for a three-day period. In three separate instances, for a total of 19 days, this animal was not located. It is likely that it had exited the boundaries of the study plot. Overall this male retraced its movements and was last seen at its site of discovery.

We observed Male #06 for a total of 34 days, beginning 2 January, during which we made actual sightings on only 11 days. This male was very active, traversing a 20 x 23 m area, and often crossing up to 7+ m expanses of open grass. In movements it routinely utilized the barren wood floors of the second story veranda as a walkway. Outside of the observation period it was once found bisecting the obstacle of the house via a 6-m walk through the living room, which opened to the opposite veranda. We observed this male mating with Female #01 on two separate occasions (one outside of its 34 day observation period); for a detailed account see Herrmann and Solèr-Kühni (2005). It was also observed attending an unknown female at another location.

Although the number of chameleons and duration of these observations limit conclusions, several trends can be noted. Our observations on *C. montium* are similar to those of Hebrard and Madsen (1984). While working with *Chameleo dilepis*, a chameleon species from a wooded grassland, they found that although both sexes moved between shrubs, females were more sedentary than males. They report females residing in one bush for up to 48 days, though the area of the bush is not presented. In comparison, *C. montium* Female #01 resided in her 4 x 5 m tree/bush area for 133 out of 140 days. Female #02 resided a 2 x 3 m vine growth area for 51 consecutive days. This suggests that the prey base available there was sufficient to meet their needs. Less energy expenditure, devoted to travel, should be advantageous for other needs such as egg production. Additionally, the risk to predators would be reduced by a more sessile existence.

The motivation for Female #03 to relocate repeatedly is perplexing. She was observed in the vicinity of both male and female chameleons, however, did not relocate immediately; thus, being 'run off' seems unlikely.

Neças (1995) reports that in general male chameleons tend to have territories that are respected. In contrast, all three male *C. montium* in this study shared their territory with at least one of the other study males. Hebrard and Madsen (1984) note that the size and shape of a *C. dilepis* male's home range is determined largely by the number and location of females with whom the males interacted. Cuadradro (2001) found that *Chameleo chameleon* males guard receptive females and follow them throughout their habitat. For females that moved long distances, they defined the male's territory as an 'umbrella territory' which consisted of what ever area the guarded female was occupying. Male *C. chameleon* often guard their females for periods of up to 20 days, or even longer. In comparison, *C. montium* guard their females for a relatively short period of time, three days. However, our observations suggest that here too the females are the guarded territory rather than the actual area. No male-male interactions were observed through out the duration of this study.

Movements across open habitat are recorded for chameleons such as *C. dilepis* (Hebrard and Madsen 1984) and for *C. chameleon* (Cuadrado 2001), which can travel distances of up to several hundred meters per day; however, these are open habitat species, thus across the ground movements are assuredly a necessity.

Though dietary analysis has suggested *C. montium* to occasionally forage near the ground (Hofer et al. 2003) and it is known that females must descend for egg laying, our observations of this forest species to readily and routinely utilize such barren expanses is somewhat surprising. Total territory estimates for this species must be executed with caution because of the tendency for some animals to remain stationary for extended periods of time and then spontaneously relocate to distances relatively far. Models based upon movements of lizards and mathematical formulas used to interpret the number of sightings required to determine home range of lizards (Christian and Waldschmidt 1984; Rose 1982; Stone and Baird 2002) might not fit for this species.

Acknowledgments.—We thank the Cameroon Ministry of Scientific and Technical Research (MINREST) and the Ministry of Environmental and Forestry (MINEF) for granting permits. We thank Martin Etuge for identifying plants, and H-W. Herrmann and T. Edwards for providing valuable comments on the manuscript.

Nest construction requires time and energy investment and different defensive strategies are known for the protection of these structures. In social insects like termites, some species invest a great amount of energy constructing nests that are resistant to the attack of vertebrate predators, while other species show low investment in building activities, but nest fortification and nest defense is accomplished by toxic soldier secretions (Coles and Howse 1983). Among vertebrates with nests built solely or mainly by one sex, several features of the construction may reveal or amplify characteristics of the builder to potential mates (see Barber et al. 2001).

Frogs of the *Leptodactylus fuscus* group comprise about 25 species (Frost 2004) that build subterranean chambers used for the deposition of eggs enclosed in foam (Heyer 1969). However, the architecture of the subterranean nests has been described for only a few species (e.g., Crump 1995; Giaretta and Kokubum 2004; Martins 1988; Sazima 1975; Sazima and Bokermann 1978). The evolution of such specialized nest structures in anurans is generally related to avoidance of aquatic predators on eggs and embryos, prevention of desiccation of eggs and larvae, and protection of adults from visually-oriented predators (e.g., Haddad and Sawaya 2000; Heyer 1969; Prado et al. 2002). We describe the subterranean nests of three *Leptodactylus* species in the *fuscus* group: *L. fuscus*, for which nests are well-known from several South American regions; and *L. notoaktites* and *L. mystaceus*, for which we describe nests for the first time.

Methods.—Nests of *L. fuscus* were recorded in the southern Pantanal, municipality of Corumbá (19°34'S, 57°00'W), State of Mato Grosso do Sul, southwestern Brazil, in November 1997 and November 2000. Nests of *L. notoaktites* were recorded in the State of São Paulo, southeastern Brazil, in the municipalities of Barra do Turvo (24°56'S, 48°25'W) and between Iporanga and Apiaí (24°33'S, 48°40'W) in September 2003, and Ribeirão Branco (24°21'S, 48°44'W) in January 2004. Nests of *L. mystaceus* were recorded in the municipalities of Areia (06°58'S, 35°41'W), State of Paraíba, northeastern Brazil, in April 1993, and Rio Claro (22°16'S, 47°42'W), State of São Paulo, southeastern Brazil, in October 2001.

Results.—Nests of *L. fuscus* in the Pantanal (N = 2) were observed being constructed by males on muddy soil at the edge of temporary ponds. They had an access tunnel 5–30 cm long and 2.5 cm wide ending in an oval chamber (4.5 cm high, 5.4 cm wide). On 05 November 2000, males started to call at late afternoon (1900 h) from the muddy edge of a puddle. The first nest was built by a male between 2000 and 2055 h, in the same way described by Martins (1988). Then, this male started to emit advertisement calls at a distance of about 1.0 m from the nest access opening. The second nest was built by another male between 2100 and 2130 h; subsequently it started to call at a position 1.5 m from the nest. The distance between these nests was about 0.5 m and the whole process lasted 55 and 30 min, respectively. On 14 November 1997 we found a nest access near a calling male. Digging along the access tunnel we found an empty chamber (5.0 cm high, 5.5 cm wide). We dug a little more and found a second chamber (5.1 cm high, 5.3 cm wide) containing foam with tadpoles. After further digging we found two additional chambers, with similar sizes, also with foam and tadpoles. We could not find any access to these three chambers with tadpoles and they seemed completely closed.

Nests of *L. notoaktites* (N = 3) had two chambers. The first one was smaller (6.5 cm long, 3.0 cm wide, 1.8 high) than the second (7.5 cm long, 7.5 cm wide, 5.5 cm high) and both were interconnected; although no tunnel was present, these chambers were adjacent to each other with a constriction between them. The males apparently were emitting advertisement calls from the first, smaller chamber. These nests had only one opening measuring 1.9 cm wide.

For *L. mystaceus*, we recorded two nests. One was found in northeastern Brazil and exhibited a complex structure (Fig. 1). It had one access opening and three chambers connected by tunnels. In this subterranean system, the first two chambers were empty and foam containing eggs was in the last chamber (Fig. 1). This subterranean nest was built during the first rains on muddy and wet soil in a temporary pond in an upland forest, before the pond had filled. The second nest was observed in southeastern Brazil. It consisted of one access opening and an oval chamber without a tunnel.

Discussion.—Similar to the *L. fuscus* nests we report in the Pantanal, Martins (1988) observed subterranean nests of this species in the State of Roraima, northern Brazil. These nests consistently are comprised of a single access and a tunnel connecting the opening with a subterranean chamber. The tunnel is large enough to allow the entrance of only one individual, whereas the size of the chamber permits the occurrence of amplex and oviposition. Sazima (1975) and Gonsales (2004) described the same nest structure for *L. fuscus* (referred as *L. sibilatrix* by Sazima 1975) from different populations in the State of São Paulo, southeastern Brazil. Due to the highly territorial nature of these frogs, the most likely explanation for the "four-chambered" nest we describe is that the four chambers were dug out by the same male, and sealed after egg-laying.

Although not observed in the Pantanal, females of *L. fuscus* were recorded sealing the nest opening after oviposition in the State of São Paulo (Gonsales 2004). For *L. bufonius* in Argentina, females

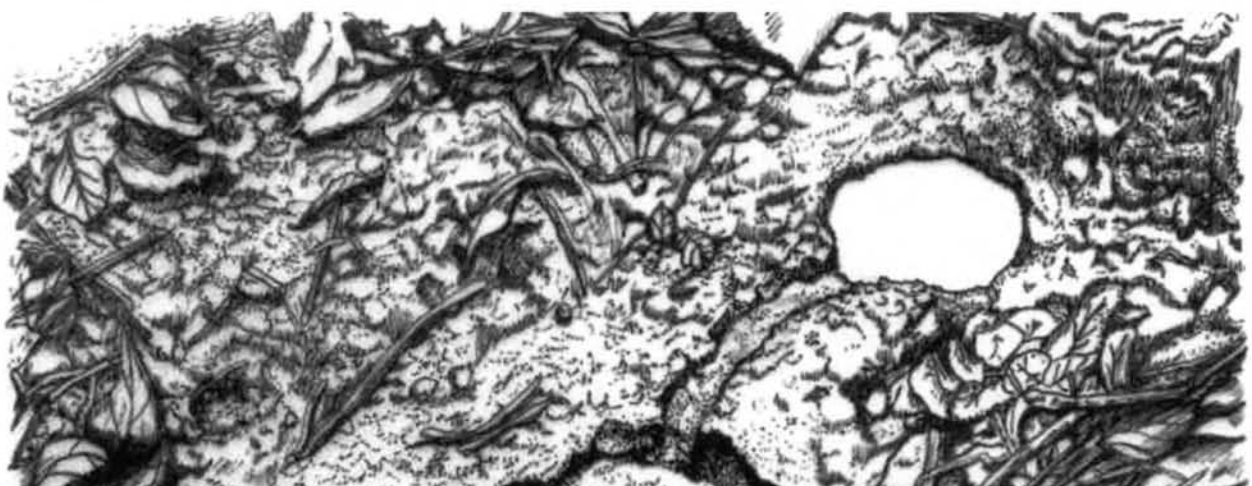

FIG 1. A cross-sectional view of an excavated subterranean nest of *Leptodactylus mystaceus*, showing one access tunnel (arrow) and three chambers connected by tunnels. Note that only the last chamber (right) is filled with a foam nest.

also were recorded sealing the nest opening after oviposition (Crump 1995, Reading and Jofré 2003). Sealing of the nest tunnel after oviposition was recorded for a few nests of *L. camaquara*, which digs its nest under rock slabs, as well as for *L. cunicularius*, which builds a globular nest and seals the roof access after oviposition takes place (Sazima and Bokermann 1978, I. Sazima pers. comm.). However, the sex responsible for the sealing in these two species was not documented.

Nest building by *Leptodactylus* of the *L. fuscus* group may occur in different soil types, such as sand (Arzabe and Almeida 1997) or mud (Reading and Jofré 2003). We found that nest digging took 30 and 55 min. Martins (1988) also recorded one nest being dug over 40 min by a *L. fuscus* male on muddy soil. The time spent in building activities varies from 10 min in *L. troglodytes* on sand (Arzabe and Almeida 1997) to 90 min in *L. bufonius* on mud (Reading and Jofré 2003). It appears that construction of nests on mud takes longer. We suggest that total time needed to dig a nest is related with soil type and nest architecture.

The nest architecture varies considerably among the species of the *L. fuscus* group. The presence of at least one additional chamber, as described here for *L. notoaktites* and one nest of *L. mystaceus*, also has been recorded for other *Leptodactylus* species, such as *L. albilabris*, *L. latinasus*, and also may occur in *L. fuscus* nests (see Solano 1987). The nest of *L. mystacinus* is an elliptical chamber with a short tunnel and access opening partly or totally sealed (Sazima 1975). The nests of five *Leptodactylus* of the *fuscus* group from open areas in southeastern and central Brazil were described by Sazima and Bokermann (1978). *Leptodactylus furnarius* builds a half oval nest with no tunnel and seals it at the top after egg-laying; *L. jolyi* builds a sinuous corridor connecting the chamber and does not seal the access; *L. cunicularius*, *L. camaquara,* and *L. tapiti* dig their nests under rock slabs, the two latter species with the chamber connected to a short tunnel with the opening facing streams at sites subject to periodical floods (Sazima and Bokermann 1978, I. Sazima pers. comm.). The nest of *L. cunicularius* has a long tunnel compared to the other four above-mentioned species, and is dug in slopes far from temporary streamlets, to which the tadpoles are carried by water draining the slopes (Sazima and Bokermann 1978, I. Sazima pers. comm.). The nest of *L. troglodytes* that lives in open areas has two access openings (Arzabe and Almeida 1997). The nest of *L. bufonius* is described as cone-shaped and extends up to 5.5 cm above the ground, with an opening in the upper part of the cone (Crump 1995).

Subterranean nests and their variable nest architectures may serve several purposes, including an antipredation function. Several invertebrates and vertebrates prey on frogs, mainly during their reproductive activity (e.g., Haddad and Bastos 1997, Prado 2003, Toledo 2003). Hawks and snakes have been reported preying on adults of *Leptodactylus* species of the *fuscus* group at reproductive sites (Arzabe and Almeida 1997, Giaretta and Kokubum 2004). Giaretta and Kokubum (2004) recorded a colubrid snake inside a nest chamber of *L. furnarius*; it was a juvenile *Liophis meridionalis* which contained 17 tadpoles in its stomach. Gonsales (2004) observed eggs and tadpoles of *L. fuscus* and *L. mystacinus* being eaten by ants of the genus *Camponotus* that were inside the chambers. The hylid *Hyla leucopygia* also builds subterranean chambers, and Haddad and Sawaya (2000) observed a colubrid snake, *Liophis miliaris*, preying on a pair of adults inside the chamber. Haddad and Sawaya (2000) commented upon the evolution of this specialized reproductive mode in hylids, and suggested that adults, eggs, and embryos are probably more protected from strictly aquatic predators and from visually oriented terrestrial predators in these subterranean nests. However, predators oriented by olfaction, such as snakes, can find concealed subterranean nests (Haddad and Sawaya 2000). Additionally, several invertebrates, such as ants (Gonsales 2004), spiders (Villa et al. 1982), and fly larvae (Downie et al. 1995) also seem to be important predators within concealed subterranean nests of *Leptodactylus* species. The presence of two access openings, as recorded for one nest of *L. troglodytes* (Arzabe and Almeida 1997), may allow the frog to escape from a predator entering the subterranean chamber. The presence of two or more chambers in the nests of *L. notoaktites* and *L. mystaceus* may be built to accommodate additional clutches, as reported for *L. fuscus* in this study, but additionally may have evolved into a more complex structure, increasing the frog's chances of fleeing from predators.

Calling from within the nest, as recorded herein for *L. notoaktites*, as well as for *L. fuscus* (Martins 1988), and *L. bufonius* (Reading and Jofré 2003), may protect males from predators during calling activity, when they are exposed to predation. It is also important to note that the construction of the subterranean chambers may initiate both after or before female approach, depending on the species (Sazima 1975, Martins 1988). Sazima (1975) suggested that when nest initiation occurs after female approach, the distance kept among males is apparently smaller compared to species that build the nests before the approach of the female. This suggests that when nests are built before female approach, as observed here for *L. fuscus* and *L. notoaktites*, nests may have other functions than only protecting the foams, such as shelter sites, reinforcing territorial behavior in these species.

Another selective pressure molding nest architecture in *Leptodactylus* may be related to habitat type. Open or forested areas may exert different selective pressures during breeding. These may include the exposure of frogs to visually-oriented predators, as recorded for rodents by Jackson (2000). Also, thermal differences and different soil types may be other factors related to nest architectures of species in the *L. fuscus* group.

Acknowledgments.—We are very grateful to W. Ronald Heyer, Célio F.B. Haddad, and L. Felipe Toledo for critically reading the earlier drafts of the manuscript, Ivan Sazima for the valuable suggestions and important information which helped us to improve the text, and Washington L.S. Vieira for the drawing. We also thank Célio F.B. Haddad, L. Felipe Toledo, and Luciana Lugli for providing some data on *L. mystaceus* nests and W. Ronald Heyer, Marcelo N.C. Kokubum, and Deanna H. Olson for the valuable suggestions on the final versions of the manuscript. C. Arzabe thanks CNPq for the graduate fellowship. C.P.A. Prado acknowledges Luís O.M. Giasson and L. Felipe Toledo for field assistance, the CNPq for graduate fellowship (proc. 140397/2000-0), FAPESP for the post-doc fellowship (proc. 04/00709-0), and the Biota FAPESP (proc. 01/13341-3), CNPq, and Fundação O Boticário de Proteção à Natureza (proc. 0570/20022) for financial support. Research permits were authorized by IBAMA (proc. 02001.000636/01-86, license # 018/02) and Instituto Florestal do Estado de São Paulo (Autos # 42.455/2002).

One strategy to enhance small populations of crocodilians is to release captive-reared individuals into the wild. However, information is scarce on the success of relocated and translocated animals (Dodd and Siegel 1991). There are concerns about released animals and their ability to hunt for food and adapt to their environment (Blake and Loveridge 1975) that might result in low survivorship following release. Low survivorship would result in very poor recruitment of captive-reared animals as compared to wild crocodilians.

Despite these concerns, successful recruitment of captive-reared females into wild breeding populations has been demonstrated for *Crocodylus palustris* (Choundhury 1981), *C. porosus* (Kar 1996), *C. intermedius* (J. Thorbjarnarson, pers. comm.), and *Alligator mississippiensis* (Elsey et al. 2000a, 2000b). In most of these programs animals are released at 1.0–1.5 m total length (TL), after 2–4 years of captive rearing.

Sexual maturity is an important variable in population dynamics and is a useful datum for conservation programs, such as Proyecto Yacaré (MAGIC/MUPCN), that are attempting to facilitate the recovery of crocodilian populations. Since 1990, Proyecto Yacaré (*Caiman* Project), has been working to enhance the wild population of *Caiman latirostris* in Santa Fe Province, Argentina. We collect eggs from wild nests soon after laying (December–January) and artificially incubate the eggs. Hatching occurs during February and March. Hatchlings are marked by removing selected caudal scutes (indicating hatching year and nest of origin). Hatchlings are raised in concrete pools until November; therefore animals are kept in captivity for a maximum of nine months, and reach an average size of 45 cm TL prior to release. They are then reintroduced in the same place where the eggs were collected. While in captivity, animals are fed chicken *ad libitum*, supplemented with vitamins and minerals, three times a week (for details see Larriera 1993).

Caiman latirostris reaches maximum latitudinal range in Argentina at Santa Fe Province, Argentina (31°S, 60°W). Crocodilian growth rates vary among habitats (Magnusson and Sanaiotti 1995), and latitudinally (Ferguson 1985). In a species such as *C. latirostris* with wide latitudinal distribution, reaching the border between Paraíba and Rio Grande do Norte states in northeastern Brazil (7°S) to Rio Grande do Sul (southernmost point of Brazil, 34°S; Verdade et al. 2003); if size is a determinant for reproduction, then more equatorial populations would grow faster and possibly reproduce earlier than higher latitudinal ones.

Limited data are available on age at sexual maturity in crocodilians. Available information about age of first reproduction in *C. latirostris* is limited to two papers recently published, but they referred to captive animals in São Paulo (Verdade and Sarkis 1998; Verdade et al. 2003). The earlier study suggested nine years as the minimum age for reproduction. The later study documented reproduction at an age of five years for a female kept in a greenhouse from day 55 of age to day 430. After that, the female was moved to an open outdoor enclosure. At first reproduction, this female was 81.0 cm (snout–vent length), 19.8 kg (body mass, Verdade et al. 2003), and aged five years (4 years, 11 months, 27 days).

Materials and Methods.—We captured 14 females at their nests in the wild in San Cristóbal County, Santa Fe Province, Argentina (30°15'S, 60°50'W), during summer 2001–2002. Animals were snared while displaying defensive behavior at their nests. Of those 14 animals, seven were marked females of known age and part of the released stock of *C. latirostris* from Proyecto Yacaré. We assumed that a female caiman attending a nest was the maternal parent of the clutch in the respective nest. Recent results confirmed the assumption that attending alligators are maternal parents of the respective nests (Davis et al. 2001).

Once caught, the farm-released females were measured to the nearest cm in total length (TL) and weighed with a 0.1 kg precision scale. We did not weigh the wild females, because they exceeded the maximum capacity (20 kg) of our scale. The eggs from the nest were collected and transported to the laboratory where we weighed each clutch and calculated mean egg mass (clutch weight/clutch size; precision 0.05 kg). Eggs were incubated at 31.5°C and 95% relative humidity until hatching.

In this paper we present information on female age, body mass (BM), total length (TL), clutch mass, clutch size, egg mass, and hatching success (# of hatchlings/clutch size). We also compared female TL and body mass (known age females and unknown age captured females), clutch size of the seven females and a subset (N = 31 nests) from the total nests harvested in the season (N = 196) and hatching success of the seven females vs. a subset of eleven nests of the same season with a non-parametric ANOVA (Kruskal-Wallis test). Because hatching success could be affected by inappropriate handling during collection (Larriera 1995; Woodward et al. 1989), in this comparison we used only nests that were collected at the same locations, at the same time, such that all eggs were subjected to the identical conditions before, during, and after collection.

Results.—Five of the previously marked females were nine years old, the remaining two were ten years old (Table 1). Females nested within 1 km of their release point nine or ten years earlier. No female moved far from the place were it was released, although there are many lagoons and rivers in the area.

Clutch size of the seven released females was similar to a subset of data from wild clutches ($H = 1.28$; $P = 0.257$), and there was no difference in hatching success ($H = 0.00218$; $P = 0.6114$). The 'head-started' females captured were shorter than the other seven unmarked females captured (152 ± 6 cm vs. 178 ± 17 cm; $H = 6.53$; $P = 0.0082$). Females in this study weighed less than those reported by Verdade and Sarkis (1998) and Verdade et al. (2003), with a body mass of 15.7 ± 3.2 kg vs. 24.8 ± 5.1 kg ($H = 7.01$, $P = 0.0065$). The largest wild female captured in this study was as heavy as the smallest female (five years old) in Verdade et al. (2003).

Discussion.—Our results indicate that releasing yearling *Caiman latirostris* can successfully provide a source of recruitment of breeders to the wild populations. Half of the females we caught this season were reintroduced by Proyecto Yacaré. Although the marked females were smaller in total length than wild females, because clutch size and hatching success was similar to unknown-age females, we speculate that the 'head-start' females may be competent reproducers in the wild. This is the first report of reproduction of wild farm-released female *C. latirostris* of known age.

Female age at sexual maturity in the wild, after nine months of 'head-start' rearing, was the same as previously reported by Verdade and Sarkis (1998) for captive *Caiman latirostris*. In Verdade et al. (2003), one female was five years at first reproduction, but it was kept in a greenhouse during the first two winters.

TABLE 1. Data for seven marked, known-age females caught during nest defense. In the last row we present averages ± St. Dev. BM = body mass; TL = total length; egg mass = clutch mass/clutch size; and hatching success = # of hatchlings/clutch size.

Nests	Body mass (kg)	TL (cm) (g)	Clutch mass (mean, g)	Clutch size	Egg mass (mean, g)	Hatching success (%)	Age (years)
1	17.0	154	2100	36	58.3	83.33	10
2	18.5	156	2050	37	55.4	48.65	10
3	19.8	163	2700	41	65.9	85.37	9
4	12.4	147	1700	30	56.7	66.67	9
5	12.8	148	1850	30	61.7	43.44	9
6	13.6	148	No data	26	No data	69.23	9
7	17.0	151	2050	35	58.6	100	9
Mean	15.7 ± 3.2	152.4 ± 5.7	2075 ± 342	33.6 ± 5.1	59.4 ± 3.8	70.96 ± 20.33	9.3 ± 0.5

In a wild population Moulton et al. (1999) suggested a conservative snout vent length of 75 cm, and 8.6 to 15 years for *C. latirostris* to first reproduction. The females in our study are of comparable age, and of the same size (assuming SVL = 0.5 TL). Based on the data of this study as well as Verdade and Sarkis (1998) and Verdade et al. (2003), mature female *Caiman latirostris* are at least five years old and weigh at least 12.4 kg.

Farm-reared female *Alligator mississippiensis* released when one year old and 79–99 cm TL, began to reproduce at around seven years, but females that were 132–142 cm TL at release reproduced at around six years (Elsey et al. 2000b). Hatchlings produced in the wild, with no 'head-start' could take longer to breed, because many farm-released juvenile alligators grew faster than wild ones (Elsey et al. 1992, 2000). If maturity is related to growth rate, then the farm-released animals would more quickly become breeding stock in the wild population than wild-hatched animals.

Size classes regularly used for monitoring *Caiman latirostris* populations are based on the ones proposed for *Caiman crocodilus* by Gorzula (Waller and Micucci 1993). In this system, class III animals range from 1.3 to 1.7 m total length and include sexually mature males and females. Class IV should only include mature males, but not females. Because we captured a wild female that was 1.95 m, we suggest that this size class system is not appropriate for *Caiman latirostris*. We propose a class III size range of 1.3 to 1.95 m for *Caiman latirostris*. We also recommend that all crocodilian species subject to hunting of class IV animals based on size classes determined for other species be evaluated in order to avoid hunting the biggest females, since they produce bigger clutches with bigger eggs (Larriera et al. 2004).

Acknowledgments.— We thank the entire crew of Proyecto Yacaré (P. Donayo, P. Amavet, M. Medina, E. Gallo and V. Parachú) who helped during egg collection, incubation, and hatching. We are thankful to Luciano Verdade for his ideas and comments on the manuscript. Ruth Elsey and Phil Wilkinson helped with English revision and comments on the manuscript. Yacarés Santafesinos (MUPCN), Programa sobre la Biodiversidad del Litoral Fluvial Argentino (Secyt), and PICT # 11928 supported the present study. This is the publication # 58 from Proyecto Yacaré.

SEMINATRIX PYGAEA (Black Swamp Snake). **REPRODUCTION.** Previous reports of litter size in *Seminatrix pygaea* range from 2 to 15 and were determined primarily by counting the number of enlarged follicles or embryos during palpation or dissection (Gibbons and Dorcas 2004. North American Watersnakes: A Natural History. University of Oklahoma Press, Norman. 438 pp.). During July 2004, three of 15 pregnant females gave birth to record size litters (16, 19, and 22). Pregnant *S. pygaea* were collected between 27 May and 1 June 2004 from Ellenton Bay (Savannah River Site, South Carolina) using aquatic minnow traps. All snakes were housed individually in the laboratory at 27°C and offered salamander larvae (*Ambystoma talpoideum*) every 7–10 days until they gave birth. Within 24 h of parturition I measured the mass (nearest 0.01 g), SVL (nearest mm), and tail length (nearest mm) of the mother and all neonates. Total litter mass (TLM, all neonates together) was measured and used to calculate reproductive investment (relative clutch mass) by dividing the post-partum maternal mass by the total litter mass (Shine 1980. Oecologia 46:92–100). All neonatal values are presented as mean ± 1 SE. Because of their small size at birth, it was not possible to safely sex the neonates by probing; therefore I relied on relative tail length to sex the neonates (Dodd 1993. Can. J. Zool. 71:1281–1288). On 17 July a female (post-partum mass = 33.90, SVL = 363) gave birth to 22 neonates (TLM = 28.36, mass = 1.29 + 0.02; SVL = 108.9 ± 0.62; 9 Females: 13 Males). On 20 July a litter of 16 neonates (TLM = 22.41, mass = 1.40 ± 0.03; SVL = 112.8 ± 0.75; 7F: 9M) was born to a second female (post-partum mass = 29.23, SVL = 354). Lastly, on 25 July a female (post-partum mass = 33.25, SVL = 383) gave birth to 19 neonates (TLM = 18.81, mass = 0.99 ± 0.02; SVL = 101.5 ± 0.93; 13F: 6M). All three mothers expended a large reproductive effort as indicated by high relative clutch masses (0.84, 0.77, and 0.57 respectively). None of the litters contained stillbirths and all snakes were returned to their original point of capture.

Financial support provided by the Environmental Remediation Sciences Division, Office of Biological and Environmental Research, U.S. Department of Energy (Award No. DE-FC09-96SR18546).

GEOGRAPHIC DISTRIBUTION

Instructions for contributors to Geographic Distribution appear in Volume 36, Number 1 (March 2005). Please note that the responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extension reports unless a thorough literature review has been completed.

DESMOGNATHUS FOLKERTSI (Dwarf Black-bellied Salamander). USA: GEORGIA: GILMER CO.: Chattahoochee National Forest, Coosa-Tallapoosa Drainage, Conasauga Creek. 8.7 miles NW of Ellijay and 0.1 miles E on Mulberry Gap Road (34.7950N, 084.6033W). 06 November 2004 and 05 February 2005. Voucher specimen University of Alabama Herpetological Museum (ALA 14878). Collected by Jessica Wooten, Zachary Felix, Deborah Merritt, and Bill Sutton. Verified by mitochondrial DNA sequences with specimens from the type locality (West Fork of Wolf Creek) in Union Co., Georgia (Camp et al. 2002. Herpetologica 58[4]:471–484). This is a range extension and new county record for this recently described species known from only six streams in Georgia (Camp 2004. Cat. Amer. Amphib. Rept. 782.1–782.3). This site was typical for this species with numerous large boulders with cascading riffles followed by still pools. Mitochondrial DNA sequences were obtained from five individuals, This specimen was collected under a scientific collecting permit (#29-WMB-03-197) issued to LJR by the Georgia Department of Natural Resources.

PLETHODON GLUTINOSUS (Northern Slimy Salamander). USA: ILLINOIS: St. Clair Co.: Sugar Loaf Township (T1S R10W, northwest quarter of section 13). 14 May 2004. Robert Weck. Verified by Chris Phillips. Illinois Natural History Survey (INHS 19541). New county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.). Adult specimen found under a log in a mature oak forest, within a region of karst topography. Four other specimens have since been observed in the same area, one within a small cave.

Submitted by **ROBERT WECK**, Department of Biology, Southwestern Illinois College, 2500 Carlyle Avenue, Belleville, Illinois 62221, USA; e-mail: bob.weck@swic.edu.

ANURA

BUFO PUNCTATUS (Red-spotted Toad). USA; TEXAS: Jones/Shackleford Co. line. Jones/Shackleford County Road 204 just S of Lueders (32°47.486'N, 99°36.752'W). 9 May 2005. J. R. Dixon. Verified by J. R. Dixon, Texas A&M University, Texas Cooperative Wildlife Collection. TCWC 89760. New county record (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station, Texas. 421 pp.) Ten male *Bufo punctatus* were calling below rock ledges, in the evening at Lake Shackleford dam and spillway. One individual was retained as a voucher. These are the first recorded specimens found on the Jones/Shackleford County line.

Submitted by **MELISSA JONES, SUSANNAH REILLY, M. R. J. FORSTNER,** and **J. R. DIXON**, Department of Biology, Texas State University at San Marcos, San Marcos, Texas 78666, USA; e-mail: mj46953@txstate.edu.

GASTROPHYRNE CAROLINENSIS (Eastern Narrow-mouthed Toad). USA: ARKANSAS: Calhoun Co.: Forested area 6.4 km N. of Hampton, Arkansas (Sec. 8, T13S, R13W). 19 May 2005. H. W. Robison. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 29399). Verified by Stanley E.Trauth. New county record in south-central Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville).

Submitted by **HENRY W. ROBISON** and **JANET RADER**, Department of Biological Sciences, Southern Arkansas University, Magnolia, Arkansas 71754-9354, USA (e-mail: hwrobison@saumag.edu).

HYLA ROSENBERGI (Medium Gladiator Treefrog). VENEZUELA: ESTADO TACHIRA: Municipio Uribante, 17 km S of Pregonero; Doradas River (7°53'N, 71°45'W), 650 m. Colección de Vertebrados Universidad de Los Andes, Mérida, (CVULA-IV 3573). ESTADO BARINAS: Sector Miraflores, 3 km from Barinitas, 600 m. (CVULA-IV 6294). Verified by G. Ollarves. Previously reported from northwestern Costa Rica, through western Panamá and western Colombia to northwestern Ecuador (Kluge 1979. Occas. Pap. Mus. Zool. Univ. Michigan 688:1–24; Duellman 2001. The Hylid Frogs of Middle America. SSAR, 1180 pp.). Presence of this species in Tachira state is not surprising because this area is connected with the lowlands of Central America and Amazonia by the Caparo Corridor (Yerena 1994. Corredores Ecológicos en los Andes de Venezuela. Parques Nacionales y Conservación Ambiental Nº 4, Editorial Torino, Caracas. P. XI +186 pp.). This is the second report of a *Hyla boans* group species from the Pacific lowlands of lower Central America in this corridor (Chacón-Ortiz et al. 2004. Rev. Acad. Colomb. Cienc. 28[108]:391–402). The specimen CVULA-IV 3573 was previously reported as *Hyla boans* in western Venezuela (Barrio 1999. Herpetol. Rev. 30:230). The first country record and easternmost known locality extends the range 700 km from Choco Department, Colombia (Lynch and Suarez 2001. Caldasia 23[2]:491–507) to Venezuela.

Submitted by **ANDRES CHACÓN-ORTIZ, CARMEN GARCIA,** and **EMMA CAMACHO**, Laboratorio de Ecología y Genética de Poblaciones, Centro de Ecología, Instituto Venezolano de Investigaciones Científicas (IVIC), Apartado Postal 21827, Caracas 1020-A, Venezuela (e-mail: aecortiz@ivic.ve; cgarcia@ivic.ve; ecamacho@ivic.ve); and **AMELIA DÍAZ DE PASCUAL**, Facultad de Ciencias, Universidad de Los Andes, Mérida, Venezuela (e-mail: adiaz@ula.ve).

HYLA SQUIRELLA (Squirrel Treefrog). USA: SOUTH CAROLINA: Pickens Co.: South Carolina Department of Natural Resources Clemson Office (153 Hopewell Road, Pendleton, South Carolina, USA). 17 June 2004. John G. Garton. Bob Campbell Museum of Natural History, Clemson University (CU 2233). Verified by Richard R. Montanucci. New county record (Martof et al. 1989. Amphibians and Reptiles of the Carolinas and Virginia. University of North Carolina Press, Chapel Hill, North Carolina). Extends the range of the species at least 120 km from nearest known localities in the lower piedmont of South Carolina (Edgefield, Richland, and Laurens counties). Specimen was collected on side of DNR building. At least two other individuals were heard calling at this locality.

Submitted by **COREY E. ROELKE**, PO Box 19498, Department of Biology, The University of Texas at Arlington, Arlington, Texas 76019, USA; e-mail: croelke@uta.edu.

PHRYNOHYAS CORIACEA (Suriname Golden-eyed Treefrog). GUYANA: POTARO-SIPARUNI: Kaieteur National Park (05°10'23"N, 59°28'52"W, ca. 350 m elevation). August 2004. Collected by local people. Royal Belgian Institute of Natural Sciences, Brussels, Belgium (IRSNB 13672). Verified by C. Lac-Hair. Adult male (60.8 mm SVL) collected in primary submontane forest of the Pakaraima uplands on white sands (ter Steege 2001. National Vegetation Map of Guyana, Guyana Forestry Commission, Georgetown). First described from Suriname, the species is also known to occur in the upper Amazon Basin in Ecuador, Peru, Bolivia, downstream to Manaus, Brazil, and in French Guiana (De

la Riva et al. 2000. Rev. Esp. Herpetol. 14:19–164; Frost 1985. Amphibian Species of the World - A Taxonomic and Geographical Reference. Allen Press and the Assoc. of Syst. Coll., Lawrence, Kansas. 732 pp.; Lescure and Marty 2000. Atlas des Amphibiens de Guyane. SPN/MNHN, Paris, Patrim. Nat. 45:1–388 ; Peters 1867. Monatsber. Preuss. Akad. Wiss. Berlin 1867:703–712; Zimmerman and Rodrigues 1990. *In* Gentry [ed.], Four Neotropical Rainforests, pp. 60–74. Yale Univ. Press, New Haven). First country record, and westernmost locality for the species on the Guiana Shield and northernmost locality in South America. This location extends the range of *P. coriacea* ca. 500 km W of the previously westernmost known locality in Suriname ("Spoorbaan") (Duellman 1971. Occ. Pap. Mus. Nat. Hist. Univ. Kansas 4:1–21).

PSEUDACRIS BRACHYPHONA (Mountain Chorus Frog). USA: TENNESSEE: Sullivan Co.: Cherokee National Forest on USFS Road 87A 100 m S of intersection with Flatwoods Roads (36°29.199'N, 82°04.303'W). 22 April 2005. Kevin Hamed. Verified by A. Floyd Scott, Austin Peay State University Museum of Zoology, APSU 17699 (voucher specimen and photo of live individual). Many individuals were calling from vegetation at the edge of a small pool created when a pit was dug to block a logging road at the intersection with USFS Road 87A. First record from Sullivan County and second record from upper East Tennessee (Redmond and Scott. 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. (Hard copy and Internet versions, the latter of which includes links to information on amphibians in Tennessee having appeared since 1996], http://www.apsu.edu/amatlas/, accessed 29 June 2005).

Submitted by **M. KEVIN HAMED**, Virginia Highlands Community College, P.O. Box 828, Abingdon, Virginia 24212, USA; e-mail: khamed@vhcc.edu.

PSEUDACRIS TRISERIATA (Western Chorus Frog). USA: ARKANSAS: Cleveland Co: Roadside ditch 6.7 km NE of Kingsland (Sec. 27, T9S, R11W). 20 March 2005. H. W. Robison. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 29400). Verified by Stanley E. Trauth. New county record in south-central Arkansas (Trauth et al. 2004. Amphibians and Reptiles of Arkansas, Univ. of Arkansas Press, Fayetteville).

Submitted by **HENRY W. ROBISON** and **JANET RADER**, Department of Biological Sciences, Southern Arkansas University, Magnolia, Arkansas 71754-9354, USA; e-mail: hwrobison@saumag.edu.

RANA FABER. THAILAND: CHANTABURI PROVINCE: Pong Nam Ron, Khao Soi Dao Tai Mountain, 1000 m elev., 27 November 1971, Sukhum Pongsapipatana. FMNH 191467–77. Verified by Robert F. Inger. First country record. Known previously only from Phnom Aural in Kampong Speu Province (type locality) and the Bokhor Mountains (= Bokor) in Kampot Province, Cambodia (Ohler et al. 2002. Raffles Bull. Zool. 50:465–481; Chuaynkern et al. 2004. Nat. Hist. J. Chulalongkorn Univ. 4:1–13). Khao Soi Dao Tai in southeastern Thailand is in a mountain range contiguous with Phnom Aural and Bokor in southwestern Cambodia, and so this record is not surprising.

Submitted by **BRYAN L. STUART,** The Field Museum, Department of Zoology, 1400 South Lake Shore Drive, Chicago, Illinois 60605-2497, USA; e-mail: bstuart@fieldmuseum.org.

RANA PALUSTRIS (Pickerel Frog). USA: ARKANSAS: Craighead Co.: County Road 762, 3.2 km W jct with Arkansas State Highway 49, ca 4.0 km NW Brookland. 29 August 2005. Jonathan W. Stanley. Verified by Chris T. McAllister. Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 29381). New county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. of Arkansas Press, Fayetteville, 421 pp.).

Submitted by **JONATHAN W. STANLEY** (e-mail: jonathanw.stanley@smail.astate.edu) and **STANLEY E. TRAUTH**, Department of Biological Sciences, P.O. Box 599, State University, Arkansas 72467, USA (e-mail: strauth@astate.edu).

RANA PALUSTRIS (Pickerel Frog). USA: GEORGIA: Whitfield Co: Dalton Middle School Campus (34°47'32.9"N, 84°56'33.1"W). 23 September 2005. Collected from a drift fence line adjacent to Mill Creek and wooded wetland. Allison Hunt. Verified by John Jensen. University of Tennessee at Chattanooga Museum of Natural History. (UTCA/GMU 4400). New county record (Williamson and Moulis 1994. Distribution of Amphibians and Reptiles in Georgia. Savannah Sci. Mus. Spec. Publ. No. 3, 712 pp.).

Submitted by **CHRIS MANIS**, **ROBERT MINTON**, and **THOMAS P. WILSON**, Department of Biological and Environmental Sciences, University of Tennessee at Chattanooga, 215 Holt Hall, Department 2653, 615 McCallie Avenue, Chattanooga, Tennessee 37403, USA; and **ALLISON HUNT**, Dalton Middle School, 1250 Cross Plains Trail, Dalton, Georgia 30721, USA.

SCAPHIOPUS HOLBROOKII (Eastern Spadefoot). USA: ILLINOIS: St. Clair Co.: Sugar Loaf Township (T1S, R10W, NW qtr of Sec. 12). 30 July 2004. Robert Weck. Verified by Chris Phillips. Illinois Natural History Survey (INHS 19542). The specimen is one of eight newly transformed juveniles observed after heavy rains. This new county record represents a northern extension of the previously known range of the species in Illinois (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Nat. Hist. Surv. Manual 8, 300 pp.).

Submitted by **ROBERT WECK**, Department of Biology, South-

western Illinois College, 2500 Carlyle Avenue, Belleville, Illinois 62221, USA; e-mail: bob.weck@swic.edu.

SCINAX ARGYREORNATUS. BRAZIL: SANTA CATARINA: Municipality of Florianópolis: Ilha de Santa Catarina, Pântano do Sul (27°46'S, 48°31'W). 07 December 2004. A. Kwet, A. F. Cordeiro, and A. Zillikens. Museu de Ciências e Tecnologia da Pontifícia Universidade Católica do Rio Grande do Sul, Porto Alegre, Brazil (MCP 8239–40). Verified by M. Di Bernardo. All specimens were observed in a small ditch with shallow water. This species was known from the coastal region of southeastern Brazil, from the states of Bahia and Espírito Santo to Rio de Janeiro and São Paulo (Silvano and Pimenta 2001. Herpetol. Rev. 32:273). A recent comment (IUCN, Conservation International, and NatureServe. 2004. Global Amphibian Assessment. <www.globalamphibians.org>. Accessed on 15 October 2004) indicates that *S. argyreornatus* might also occur in the state of Santa Catarina. However, this distribution does not include the island Ilha de Santa Catarina, and to date there are no voucher specimens cited for this state. This new record extends the distribution range about 400 km S from previous published localities.

SCINAX AROMOTHYELLA. URUGUAY: DEPARTAMENTO DE TREINTA Y TRES: Surroundings of Quebrada de los Cuervos (32°52'S; 54°28'W; 252 m elev.). 19 April 2005. C. Borteiro, C. Prigioni, and M. Tedros. Verified by D. Baldo. Colección de Batracios, Sección Zoología - Vertebrados, Facultad de Ciencias, Universidad de la República, Montevideo, Uruguay (ZVCB 11520–11521). Previously known only from Argentina: Misiones: Departamentos Guaraní, San Pedro, and Iguazú (Faivovich 2005. Herpetologica 61:69–77). First country record, extends the known range ca. 750 km S from those localities.

Submitted by **CARLOS PRIGIONI**, Secretaría de Medio Ambiente, Intendencia Municipal de Treinta y Tres, Uruguay; **CLAUDIO BORTEIRO**, Departamento de Fisiología, Facultad de Veterinaria, Universidad de la República, Uruguay; **MARCELO TEDROS,** China 2202, 12800, Montevideo, Uruguay; and **FRANCISCO KOLENC**, Cátedra de Bioquímica y Biofísica, Facultad de Odontología, Universidad de la República, Uruguay (e-mail: kolenc@adinet.com.uy).

SCINAX STAUFFERI (Stauffer's Treefrog). MEXICO: CHIAPAS: Municipality of Ocosingo, Km 140 on road from Palenque to Crucero Corozal, near border of Monte Azules Biosphere Reserve (16°45'37.1"N, 91°00'27.3"W), 151 m elev. 10 October 2004. Ricardo Paredes-León and Jorge Cime-Castillo. Colección Nacional de Anfibios y Reptiles, Instituto de Biología, UNAM (CNAR-IBH 15656–57). Verified by Elisa Cabrera Guzmán and Edmundo Pérez-Ramos. First record for the Lacandona region (Lazcano-Barrero et al. 1992. *In* Vásquez Sánchez and Ramos Olmos [eds.], Reserva de la Biósfera Montes Azules, Selva Lacandona: Investigación para su Conservación, pp. 145–171. Publ. Espec. ECOSFERA No. 1, Centro Estud. Conserv. Rec. Nat., A. C.), extending its range in Chiapas ca. 75 km SE of Palenque and ca. 52.5 km NE of Lagunas de Montebello, and ca. 85 km W of La Libertad, El Petén, Guatemala (Duellman 2001. Hylid Frogs of Middle America, 2 Vols. SSAR Contrib. Herpetol. Vol. 18, 1158 pp.). The specimens were collected from a pool in a pasture.

Submitted by **RICARDO PAREDES LEÓN**, Colección Nacional de Ácaros, Instituto de Biología, UNAM and Laboratorio de Acarología, Facultad de Ciencias, UNAM, Ciudad Universitaria, Mexico, D.F. 04510 (e-mail: skarabajo8@yahoo.com.mx); and **VICTOR-HUGO REYNOSO**, Colección Nacional de Anfibios y Reptiles, Instituto de Biología, UNAM, Ciudad Universitaria, México, D.F. (e-mail: vreynoso@ibunam.ibiologia.unam.mx).

SMILISCA CYANOSTICTA (Blue-spotted Smilisca). MÉXICO: TABASCO: Parque Estatal Agua Blanca, ca. 85 km SW from Villahermosa (17°37'10.5"N, 92°28'19.8"W; 17°37'10.2"N, 92°28' 15.1"W), ca. 80 m elev. 3 April and 21 May 2004, respectively. Marco Antonio Torrez Pérez. Colección de Anfibios y Reptiles de Tabasco, Universidad Juárez Autónoma de Tabasco (CART-00506, 00508). Verified by Marco Antonio López Luna. First record from Tabasco and a range extension of ca. 100 km NW from nearest locality, 8 km S of Palenque, Chiapas (Lee 1996. The Amphibians and Reptiles of the Yucatán Peninsula. Comstock Publ. Assoc., Cornell Univ. Press, Ithaca, New York. 500 pp.).

Submitted by **MARCO ANTONIO TORREZ PERÉZ** and **MARÍA del ROSARIO BARRAGÁN-VÁZQUEZ**, División Académica de Ciencias Biológicas, Universidad Juárez Autónoma de Tabasco, Km. 0.5 Carretera Villahermosa-Cárdenas, entronque con Bosques de Saloya, C. TELMATOBIUS CARRILLAE (Ancash Water Frog). PERU: DEPARTAMENTO LIMA: Provincia Huarochiri: Distrito Chicla: Ticlio (11°35'58.5"S, 076°11'36.6"W, 4818 m elev.). 15 February 2005. M. Lundberg. Museo de Historia Natural de San Marcos, Lima, Peru (MHNSM 19509–19516 and MHNSM 19522–23). Verified by V. Morales. Previously known only from Peruvian departments of Ancash and Huanuco (Morales 1988. Rev. Bras. Zool. 5[4]:603–608; Lehr and Fuentes 2000. Herpetol. Rev. 31:183). First department record and southernmost locality, extends the distribution ca. 180 km S from Huanuco (Lehr and Fuentes 2000, *op. cit.*).

Submitted by **CESAR AGUILAR,** Museo de Historia Natural, Departamento de Herpetología, Universidad Nacional Mayor de San Marcos, Av. Arenales 1256, Jesús María, Ap. 14-0434, Lima, Perú; and **MIKAEL LUNDBERG**, Staatliche Naturhistorische Sammlungen Dresden, Museum für Tierkunde, Königsbrücker Landstrasse 159, D-01109 Dresden, Germany.

TRIPRION PETASATUS (Yucatecan Casqueheaded Treefrog). MÉXICO: CHIAPAS: Municipality of Ocosingo, 140 km SE on the Palenque-Crucero Corozal road near Guatemalan border, 11 km S Frontera Corozal (16°45'57.3"N, 90°58'01.5"W), 171 m elev. 20 August 2004. Ricardo Paredes-León. Colección Nacional de Anfibios y Reptiles, Instituto de Biología, UNAM (CNAR-IBH 15655, CNAR-RF 22). Verified by Elisa Cabrera-Guzmán and Edmundo Pérez-Ramos. First record for Chiapas and southernmost record for México, extending range 85 km E from La Libertad, El Petén, Guatemala and 210 km from its nearest Mexican record, 7.5 km W Escárcega, Campeche (Duellman 2001. Hylid Frogs of Middle America, 2 Vols. SSAR Cont. Herpetol. Vol. 18, 1158 pp.). The specimen was collected ca. 70 cm above ground on a bush in regenerated tropical rainforest.

Submitted by **RICARDO PAREDES LEÓN**, Colección Nacional de Ácaros, Instituto de Biología, UNAM and Laboratorio de Acarología, Facultad de Ciencias, UNAM, Ciudad Universitaria, México, D. F. 94510 (e-mail: skarabajo8@yahoo.com.mx); and **VÍCTOR-HUGO REYNOSO**, Colección Nacional de Anfibios y Reptiles, Instituto de Biología, UNAM, Ciudad Universitaria, México, D.F. 04510 (e-mail: vreynoso@ibunam.ibiologia.unam.mx).

TESTUDINES

ACANTHOCHELYS MACROCEPHALA (Pantanal Swamp Turtle). BRAZIL: MATO GROSSO DO SUL: Corumbá (Nhumirim Farm: 18°57'S, 56°37'W) and Aquidauana (Rio Negro Farm: 19°34'S, 56°14'W). 1–15 October 2002. M. A. Kinas and F. L. Souza. Verified by A. S. Abe. Zoological Collection of Department Biology, Universidade Federal de Mato Grosso do Sul, Brasil (ZUFMS-CHEL: 0001–0007). Intact carapace and plastron as well as bones found around bays and salt lagoons. These are the first species records for the Mato Grosso do Sul State, better defining the Paraguay River basin as the core geographical distribution area for this species. These records are ca. 260 km straight line S from Mato Grosso State and 290 km N Puerto Casado, Paraguay, the closest locality records (Rhodin et al. 1984. Herpetologica 40:38–46).

We thank Universidade Federal de Mato Grosso do Sul and Empresa Brasileira de Pesquisa Agropecuária for financial support.

DOGANIA SUBPLANA (Malayan Softshell Turtle). PHILIPPINES: PALAWAN PROVINCE: Quezon; Barangay; Panitian; Isapa Creek. 9 December 2004. Pierre Fidenci. California Academy of Sciences Photo Voucher (CAS-HPV 37). Verified by Michelle Koo. First confirmed record for the Philippines. Two adults and two juveniles were observed at night in shaded primary forest creek (4 m wide and 0.1–0.5 m deep) with a mixture of sand, silt, gravel, and boulder as substrate. It is thus likely that this softshell turtle occurs in this region as a breeding population. Previous record of *Dogania subplana* in the Philippines was questionable because of the lack of voucher and wild populations have never been reported before (de Rooij 1915. The Reptiles of the Indo-Australian Archipelago. I. Lacertilia, Chelonia, Emydosauria, E. J. Brill, Leyden; Taylor 1920. Philippine turtles. Philippine J. Sci. 16:130–133; Iverson 1992. A Revised Checklist with Distribution Maps of the Turtles of the World. Privately Published, Richmond, Indiana).

PSEUDEMYS GORZUGI (Rio Grande River Cooter). USA: TEXAS: Brewster Co.: Rio Grande Village, Big Bend National Park (29°10.712N, 102°57.24W, 1861 ft. elevation). 19 June 2005. L. A. Bailey, J. Duvall, A. Ferguson, M. R .J. Forstner, D. Hahn, J. Jackson, V. Radhakrishnan, and S. Reilly. Verified by J. A. Campbell. University of Texas at Arlington, Amphibian and Reptile Diversity Research Center, UTA Slide Nos. 33296–33299. New county record (Dixon 2000. Amphibians and Reptiles of Texas. Second Edition. Texas A&M University Press, College Station, Texas, 421 pp.). Blood was drawn and placed in the frozen tissue collection at Texas State University (MF 17889). The adult male specimen was photo vouchered using Fujichrome Provia 100 slide film and released at the capture site, a small pond near the Rio Grande River. The specimen had a carapace length of 249 mm, a plastron length of 212 mm, a shell depth of 87 mm, and weighed 2120 g. The specimen presented reticulate melanism, a carapacial patterning found in the large males of this species. Four additional adult individuals (3M and 1F) were collected from this location during three subsequent survey months.

Submitted by **LINDLEY BAILEY, JAKE JACKSON, ADAM FERGUSON,** and **MICHAEL R.J. FORSTNER**, Department

PSEUDEMYS NELSONI (Florida Red-bellied Turtle). USA: FLORIDA: Jefferson Co.: Wacissa River, Big Blue Spring (Scott et al. 2004. Florida Geol. Surv. Bull. No. 66); 30°19'39.8"N, 83°59'05.4"W. 12 May 2005. Dale R. Jackson, Brett Stearns, and Nancy Stearns. Verified by Kenneth L. Krysko. Florida Museum of Natural History Herpetology Department photographic archive (UF 144233, five photographic vouchers). Adult male (292 mm maximum CL, 279 mm PL) caught while basking at 1330 h, released following photography. First documented record for county and Aucilla River drainage..

This specimen is the first recorded from the large distributional hiatus that remains between the Ochlockonee and Suwannee rivers (Big Bend region of Florida). Although the collection locality is a popular recreational area, the fact that the specimen was an aggressive adult casts doubt on its having been a released captive animal.

HEMIDACTYLUS MABOUIA (Cosmopolitan House Gecko). BAHAMAS: LONG ISLAND: Stella Maris (23°35.377'N, 75°15.764'W). 25, 26, 28 April 2005. Kenneth L. Krysko and Andrew P. Borgia. UF 144023–28. Verified by Josiah H. Townsend. First record for Long Island (Buckner and Franz 1994. Herpetol. Rev. 25:164). This species has also been found recently on Great Exuma Island, New Providence Island, and San Salvador Island (R. Franz, pers. comm.). Specimens were collected under bark of Australian pine trees (*Casuarina equisetifolia*) during the daytime and on building walls at night.

Submitted by **KENNETH L. KRYSKO**, Division of Herpetology, Florida Museum of Natural History, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@flmnh.ufl.edu.); and **ANDREW P. BORGIA**, P.O. Box 4346, Key West, Florida 33041, USA.

HEMIDACTYLUS MABOUIA (Cosmopolitan House Gecko). URUGUAY: DEPARTAMENTO RIVERA: Local del CeRP, km 495.500, Ruta 5, Ciudad de Rivera (30°54'S, 55°32'W). 2 August 2000. S. Umpierrez. Colección Zoología Vertebrados, Reptiles, Facultad de Ciencias, Montevideo (ZVC-R 5735, juvenile); 9 August 2001. S. Umpierrez (ZVC-R 5799, juvenile); 1 November 2001 (ZVC-R 5801, adult female) all associated with human settlements. Verified by M. D. Meneghel. The species is distributed thoroughly in South America, in Colombia, Venezuela, Guyana, Brazil, Ecuador, Peru, and Argentina (Kluge 1969. Misc. Publ. Mus. Zool., Univ. Michigan [138]:1–78; Peters and Donoso-Barros 1970. U.S. Natl. Mus. Bull. 297:1–293; Vanzolini 1978. Papéis Avulsos Zool., S. Paulo 31[20]:307–343; Cei 1993. Museo Regionale di Scienze Naturali, Torino, Monografía 14. 949 pp.). The species was recorded occasionally from Montevideo by accidental introduction from other countries (Achaval and Gudynas 1983. Bol. Soc. Zool. Uruguay, 2a. ép., 1:7–10; Achaval 1997. PEDECIBA, Facultad de Ciencias, Universidad de la República, Montevideo. 693 pp.). Vanzolini (1978, *op. cit.*) doubted the species presence in Uruguay and suggested that its southern limit was probably Rio Grande do Sul. This is the first record from Rivera and the presence of juveniles suggests a stable population in northern Uruguay. Extends known range more than 300 km from the nearest locality in Brazil (São Lourenço do Sul, pers. obs.) and more than 400 km from Porto Alegre, Brazil (Vanzolini 1978, *op. cit.*).

Submitted by **SANTIAGO CARREIRA** (e-mail: carreira@fcien.edu.uy) Sección Zoología Vertebrados, Facultad de Ciencias, Iguá 4225, CP 11400, Montevideo, Uruguay; **FEDERICO ACHAVAL** (e-mail: achaval@fcien.edu.uy) Sección Zoología Vertebrados, Facultad de Ciencias, Iguá 4225, CP 11400, Montevideo, Uruguay; and **SILVIA UMPIERREZ**, CeRP – Centro Regional de Profesores del Norte, Ruta 5, km 495.500, Rivera, Uruguay.

HOMONOTA UNDERWOODI (Underwood's Marked Gecko). ARGENTINA: RIO NEGRO: GENERAL ROCA: Villa Regina. 22 January 2005. C. H. F. Perez. Museo de La Plata herpetological collection (MLP.S 2575, 2585). Verified by J. C. Acosta. Previously known from localities in the Monte region of Catamarca, La Rioja, San Juan, San Luis, Mendoza, and La Pampa provinces (Cei 1993. Reptiles del Norte, Centro-este y Este de la Argentina. Mus. Reg. Sci. Nat. Mon. IV. 929 pp.). First provincial record and southernmost record for the species, extends the known distribution ca. 200 km S from the nearest record in La Pampa Province (Tiranti and Avila 1997. Bull. Maryland Herpetol. Soc. 33:97–117).

Submitted by **DANIEL R. PEREZ**, Universidad Nacional del Comahue, Buenos Aires 1400, 8300, Neuquén, Argentina; **CRISTIAN HERNAN FULVIO PEREZ**, Agustin Alvarez 1182 A, 8000, Bahia Blanca (Buenos Aires), Argentina; and **LUCIANO JAVIER AVILA**, CENPAT-CONICET, Boulevard Almirante Brown s/n, U9120ACV, Puerto Madryn (Chubut), Argentina (e-mail: avila@cenpat.edu.ar).

SCELOPORUS SERRIFER (Blue Spiny Lizard). MÉXICO: CHIAPAS: Municipality of Ocosingo, Frontera Corozal (16°48' 32.5"N, 90°52'44.1"W), 124 m elev. 3 May 2004. Ricardo Paredes-León and José Luis Castelo-Calvillo. Colección Nacional de Anfibios y Reptiles, Instituto de Biología, UNAM (CNAR-IBH 15662). Yaxchilán archeological site (16°54'08.3"N, 90°58'00.5"W), 219 m elev. 15 July 2004. José Luis Castelo-Calvillo. CNAR-RF 23 (photographic voucher). Both verified by Norberto Martínez-Méndoza and Edmundo Pérez-Ramos. First records for Chiapas and Lacandona region, although Lee (1996. The Amphibians and Reptiles of the Yucatán Peninsula. Comstock Publ Assoc., Cornell Univ. Press, Ithaca, 500 pp.) mentions several records close to our localities directly across the Usumacinta River in Guatemala; the closest Mexican record is 77 km N at Tenosique, Tabasco. Previous records of *S. serrifer* in Chiapas refer to a highland species, *S. prezygous* (Wiens and Reeder 1997. Herpetol. Monog. 11:1–101). Both specimens were found in uninhabited buildings.

Submitted by **RICARDO PAREDES LEÓN**, Colección Nacional de Ácaros, Instituto de Biología and Laboratorio de Acarología, Facultad de Ciencias, UNAM, Ciudad Universitaria, México, D. LAMPROPELTIS CALLIGASTER CALLIGASTER (Prairie Kingsnake). USA: TEXAS: Guadalupe Co.: 4.3 km N Jct FM 1978 and Old Seguin Road on Old Seguin Road (29°47'33"N, 97°56'12"W). 4 July 2005. Adam W. Ferguson. Verified by Jonathan A. Campbell. University of Texas at Arlington, Amphibian and Reptile Diversity Research Center. UTA Slide Nos. 33292–33295. New county record (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station, Texas. 421 pp). This adult female was captured in a funnel trap placed along a permanent drift fence array at our study site in Guadalupe County, Texas. The specimen had a snout–vent length of 832.0 mm, a tail length of 132.0 mm, and weighed 186 g. Blood was drawn and placed in the frozen tissue collection at Texas State University-San Marcos (MF 17943) and the specimen was photo vouchered using Fujichrome Provia 100 slide film.

Submitted by **ADAM W. FERGUSON** and **M. R. J. FORSTNER**, Department of Biology, Texas State University, 601 University Drive, San Marcos, Texas 78666, USA; e-mail (AWF): af1021@txstate.edu.

LAMPROPELTIS TRIANGULUM TAYLORI (Utah Milk Snake) USA: NEVADA: Elko Co.: Alt Route 93, 25 miles NE of Lages Station. ca. 1765 m elev. August 2003. Paul Lynum. Verified by Barry Sinervo. Museum of Vertebrate Zoology (MVZ 249826, three photo vouchers). Live specimen is currently being maintained at the University of California, Santa Cruz. This animal was found on the road at night during the monsoon season, in an area of mostly flat to gently rolling grassland with patches of sagebrush. First documented record for the state of Nevada. Scale meristics: dorsal scale rows 23, ventrals 204, subcaudals 49, supralabials 7, infralabials 8, triads 34. This specimen exhibits color pattern and scale meristics typical of *L. t. taylori* (Stebbins 2003. Western Reptiles and Amphibians, Houghton Mifflin Co., Boston, Massachusetts. 533 pp.). This specimen probably represents a population associated with those in western Utah.

Submitted by **MITCHELL MULKS**, Department of Ecology and Evolutionary Biology, University of California at Santa Cruz, Santa Cruz, California 95064, USA; e-mail: mulks@biology.ucsc.edu.

MASTICOPHUS SCHOTTI SCHOTTI (Schott's Whipsnake). USA: TEXAS: Wilson Co.: Eagle Creek Ranch Subdivision, nr intersection of Wild Flower and Palo Alto; 29°15.339'N, 98°12.668'W. 4 Aug 2005. Dead adult collected at 0730 h on road (Palo Alto). TNHC 64145. Verified by Travis LaDuc. First county record; fills gap along northeastern edge of range between Karnes and Bexar counties (Dixon 2000. Amphibians and Reptiles of Texas, 2nd edition, Texas A&M University Press, 421 pp.). Author has observed, but was unable to collect, two live *M. s. schotti* adults in the immediate vicinity of this location since 2001. Werler and Dixon (2000. Texas Snakes. University of Texas Press, Austin, Texas 437 pp.) report the range of this taxon is restricted to the mesquite savannah and thornbrush woodland of the Rio Grande Plain of South Texas. The Wilson County specimens occurred in a strip of Post Oak savannah that follows the outcrop of the Carrizo Sands formation through Wilson, southeastern Bexar, and into Atascosa counties. Werler and Dixon (2000, *op. cit.*) depict location records for this species in southeastern Bexar County, within ten miles of this Wilson County location.

Submitted by **FRANZ J. SCHMIDT**, 562 Cherry Ridge, Floresville, Texas 78114, USA.

NERODIA ERYTHROGASTER (Red-bellied Watersnake). USA: SOUTH CAROLINA: Anderson Co.: Approximately 2.5 km W of intersection of Dobbins Bridge Rd. and Lebanon Rd, Pendleton. 18 June 2004. Corey E. Roelke. Bob Campbell Museum of Natural History, Clemson University (CU 2199). Verified by Richard R. Montanucci. New county record. Extension of known range of the species into the Piedmont of South Carolina west and north of

previous records in Greenville and Abbeville counties, South Carolina (Martof et al. 1989. Amphibians and Reptiles of the Carolinas and Virginia. University of North Carolina Press, Chapel Hill, North Carolina). Specimen was found basking near a garden pond at a rural residence, at least 0.75 km from the nearest other permanent water.

Additional Reptile and Amphibian Range Extensions for Milne Bay Province, Papua New Guinea

e-mail: fkraus@hawaii.edu

and

GLENN SHEA
[2]Faculty of Veterinary Science B01, University of Sydney
NSW 2006, Australia

The southeasternmost region of Papua New Guinea is contained within Milne Bay Province, which consists of the southern extremity of the Owen Stanley Mountains, the adjacent Cloudy Mountains, and a variety of far-flung offshore islands. The herpetological collecting history of this region has briefly been summarized by Kraus and Allison (2004), who also presented a large number of range extensions and new island records for the region's herpetofauna.

The Louisiade Archipelago is the outermost island group within Milne Bay Province and has been poorly surveyed for reptiles and amphibians. It consists of three major islands – Misima (formerly known as "St. Aignan"), Sudest (also referred to as "Tagula"), and Rossel (also referred to as "Yela") – as well as a number of smaller islands lying more or less between the first two. Misima attracted early missionaries and served as the source of a handful of specimens described in the late 19th Century (Boulenger 1898a, b). More recently it has received collecting attention from biologists at the Australian Museum, South Australian Museum, and Bishop Museum, and some of the results of those efforts were presented by Kraus and Allison (2004). Similarly, Sudest and Rossel islands, farther to the southeast, were the source of occasional small collections that found their way to museums in the late 19th Century and were subsequently reported on (Boulenger, 1890, 1903; de Vis, 1892; Parker, 1934; Sprackland, 1991). Later, the Fifth Archbold Expedition collected some herpetological specimens on both Rossel and Sudest in late 1956 (Brass, 1959). Many of these specimens were subsequently described as new species by McDowell (1969), Tyler (1968), and Zweifel (1958, 1963, 1972, 2000), or included within broader taxonomic treatments (McDowell, 1967, 1972, 1979, 1984; Greer and Parker, 1974; Brown, 1991; Smith et al., 2001). Nonetheless, these collections were incidental to sustained efforts focused on plants and mammals and were not extensive. Most recently, Hiaso (2002) described a new species of *Cophixalus* collected during a short University of Papua New Guinea excursion to Sudest Island in 1992.

So as to better fill in the record of herpetological diversity within Milne Bay Province, we conducted surveys of Sudest and Rossel islands in April and May 2004. Incidental to this, we were also able to visit Nimowa Island, just north of the western tip of Sudest, for two days. This effort resulted in the discovery of a large number of species new to science (N = ~30) but also in a number of new island records for previously described species. We herein report on the latter records and add a couple of additional records left out of the earlier report for Milne Bay Province (Kraus and Allison, 2004). All GPS points use the AGD66 datum.

Austrochaperina yelaensis. SUDEST ISLAND: along Gesirava River, 11.4918°S, 153.4126°E, 130 m. 16–20 April 2004. F. Kraus, G. Shea, and J. Slapcinsky. Bernice P. Bishop Museum (BPBM) 20118–123; N side Mt. Rio, 11.5082°S, 153.4309°E, 730–800 m. 23 April 2004. F. Malesa. BPBM 20124–125. First record for island; previously known only from type locality near summit of Mt. Rossel, Rossel Island (Zweifel 2000).

Boiga irregularis. SUDEST ISLAND: along Gesirava River, 11.4902°S, 153.4198°E, 150 m. 22 April 2004. F. Kraus. BPBM 20790–791. First record for Louisiade Islands (O'Shea 1996).

Cyrtodactylus loriae. MT. SIMPSON: Siyomu, 10.0145°S, 149.5970°E, 1300 m. 24 February 2003. Native collector. BPBM 17255; Bunisi, 10.0171°S, 149.6002°E, 1420 m. 27 February 2003. Native collectors. BPBM 17256–257. First records for province and range extension of ~220 km (Bauer and Henle 1994).

Dendrelaphis salomonis. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 10–20 m. 11 April 2004. J. Slapcinsky. BPBM 20837; Vutha, 11.4918°S, 153.3846°E. 24 April 2004. Native collector. BPBM 20838. Specimens are of the same melanistic variety known from Misima Island. First record for island; previously known in PNG only on Misima Island (McDowell 1984; O'Shea 1996).

Emoia atrocostata. NIMOWA ISLAND: SW portion of island around Sofuwo Mission station, 11.3161°S, 153.2335°E, 0–5 m. 7–8 May 2004. G. Shea. BPBM 19979–980. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 0–5 m. 10–29 April 2004. F. Kraus and native collectors. BPBM 19970–978. First record for each island (Brown 1991; Mys 1988).

Emoia kordoana. SUDEST ISLAND: Bwagimogimo, 11.4366°S, 153.4313°E. 11 April 2004. Native collector. BPBM 19999; along Gesirava River, 11.4918°S, 153.4126°E, 130 m. 17–25 April 2004. F. Kraus and G. Shea. BPBM 20000–001. First records for any offshore island of Milne Bay Province (Brown 1991; Mys 1988).

Emoia obscura. SUDEST ISLAND: between Araeda and Mt. Rio, 11.4540°S, 153.4237°E, 145 m. 21 April 2004. F. Malesa and M. Samson. BPBM 19990; 11.4648°S, 153.4232°E, 170 m. 27 April 2004. F. Kraus. BPBM 19991. First records for Louisiade Islands (Brown 1991; Kraus and Allison 2004; Mys 1988).

Gehyra mutilata. NIMOWA ISLAND: SW portion of island around Sofuwo Mission station, 11.3161°S, 153.2335°E, 0–5 m. 7–8 May 2004. G. Shea. BPBM 19756–758. ROSSEL ISLAND: Cheme, 11.3231°S, 154.2429°E, 0–5 m. 2–3 May 2004. F. Kraus and G. Shea. BPBM 19752, 19755; Damunu, 11.3650°S, 154.0014°E, 0–40 m. 1 May 2004. G. Shea. BPBM 19753–54. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 0–5 m. 11–29 April 2004. F. Kraus, F. Malesa, G. Shea, and J. Slapcinsky. BPBM 19745–750. First records for each island (Bauer and Henle 1994).

Gehyra oceanica. NIMOWA ISLAND: SW portion of island around Sofuwo Mission station, 11.3161°S, 153.2335°E, 0–5 m. 7–8 May 2004. G. Shea. BPBM 19770. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 0–5 m. 11–28 April 2004. F. Kraus, F. Malesa, G. Shea, and J. Slapcinsky. BPBM 19759,

19762–763; ridge above Gesirava River, 11.4864°S, 153.4148°E. 26 April 2004. Native collectors. BPBM 19760–761. First records for each island (Bauer and Henle 1994).

Gekko vittatus. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 0–10 m. 12–28 April 2004. F. Kraus and J. Slapcinsky. BPBM 19773–777. First record for island (Bauer and Henle 1994).

Hemidactylus frenatus. NIMOWA ISLAND: SW portion of island around Sofuwo Mission station, 11.3161°S, 153.2335°E, 0–5 m. 7–8 May 2004. G. Shea. BPBM 19790–793. First record for island (Bauer and Henle 1994; Kraus and Allison 2004).

Lamprolepis smaragdina. NIMOWA ISLAND: SW portion of island around Sofuwo Mission station, 11.3161°S, 153.2335°E, 0–5 m. 7–8 May 2004. G. Shea and native collectors. BPBM 20006–008. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 0–10 m. 29 April 2004. Native collector. BPBM 20005. First record for each island (de Rooij 1915; Mys 1988).

Lepidodactylus lugubris. NIMOWA ISLAND: SW portion of island around Sofuwo Mission station, 11.3161°S, 153.2335°E, 0–5 m. 7–8 May 2004. G. Shea. BPBM 19822. ROSSEL ISLAND: Cheme, 11.3231°S, 154.2429°E, 0–5 m. 2–4 May 2004. F. Kraus, G. Shea, and native collectors. BPBM 19805, 19807–821; Damunu, 11.3650°S, 154.0014°E, 0–40 m. 1 May 2004. G. Shea. BPBM 19806; Jinjo, 11.3179°S, 154.2353°E, 0–20 m. 3 May 2004. F. Malesa and G. Shea. BPBM 19801–804. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 0–10 m. 12–29 April 2004. F. Kraus. BPBM 19799–800. First records for each island (Bauer and Henle 1994).

Lepidodactylus orientalis. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 0–10 m. 28 April 2004. F. Kraus. BPBM 19794. First record for province and range extension of ~700 km from previous records around Port Moresby (Bauer and Henle 1994; Brown and Parker 1977).

Litoria infrafrenata. SUDEST ISLAND: Araeda, 11.4362°S, 153.4301°E, 0–10 m. 21 April 2004. F. Malesa. BPBM 20600. First record for island (Tyler 1968).

Sphenomorphus jobiensis. ROSSEL ISLAND: Damunu, 11.3650°S, 154.0014°E, 0–40 m. 1 May 2004. G. Shea and native collectors. BPBM 20047; S slope Mt. Rossel, 11.3555°S, 154.2246°E, 720 m. 8 May 2004. F. Kraus and native collectors. BPBM 20048–049; 11.3551°S, 154.2239°E, 640–700 m. 8 May 2004. BPBM 20050; along Wabu River, 11.3419°S, 154.2192°E, 320 m. 11 May 2004. Native collectors. BPBM 20052; along Rupu River, 11.3354°S, 154.2247°E, 280 m. 11–16 May 2004. Native collectors. BPBM 20053–054. First records for island (de Rooij 1915; Mys 1988).

Sphenomorphus minutus. SUDEST ISLAND: N slope Mt. Rio, 11.5°S, 153.4281°E, 440–630 m. 23 April 2004. F. Malesa. BPBM 20057. First record for island (Kraus and Allison 2004; Mys 1988).

Sphenomorphus solomonis. NIMOWA ISLAND: SW portion of island around Sofuwo Mission station, 11.3161°S, 153.2335°E, 0–5 m. 7–8 May 2004. G. Shea. BPBM 20084-085. First record for island (Greer and Parker 1974; Mys 1988).

Varanus finschi. MT. SIMPSON: Omunsa, 10.0290°S, 149.6266°E, 1280 m. 14 February 2003. Native collector. BPBM 17250. First record for Papuan Peninsula (Böhme et al. 1994; Ziegler et al. 1999).

Varanus indicus. MISIMA ISLAND: Liak, 10.6594°S, 152.6941°E, 0–80 m. 20 January 2003. Native collector. BPBM 17249. ROSSEL ISLAND: East Point, 11.3859°S, 154.2811°E, 0 m. 18 May 2004. Native collector. BPBM 20840–843. SUDEST ISLAND: Wele River above Kolkol Waterfall, 11.4462°S, 153.4312°E, 30 m. 13 April 2004. Native collector. BPBM 20839; ALOTAU: 4.7 km W Alotau, 10.2994°S, 150.4018°E, 10 m. 12 August 2002. F. Kraus and B. Yawi. BPBM 16054. First records for Louisiade Islands and first reliably identified mainland Milne Bay Province record since recognition of sibling species complex (Böhme et al. 1994; Ziegler et al. 1999).

Acknowledgments.—We thank C. Bernard, R. Henry, S. John, P. Lagalaga, F. Malesa, M. Samson, B. Seta, J. Slapcinsky, and J. Volo for field assistance; L. Doni, N. Doni, C. Graham, C. Kembwa, D. Mitchell, I. Yidika, Fr. T. Young, and Conservation International for logistical field assistance; C. Kishinami and K. Igeta for specimen curation; the PNG National Museum and Art Gallery for providing in-country collaborative assistance; and the PNG Department of Environment and Conservation, PNG National Research Institute, and Milne Bay Provincial Government for permission to work in Milne Bay Province. This research was supported by a grant from Conservation International and by National Science Foundation grant DEB 0103794.

New Frog Records from Laos

BRYAN L. STUART
The Field Museum, Department of Zoology, Division of Amphibians & Reptiles
1400 S. Lake Shore Drive, Chicago, Illinois 60605-2496, USA
e-mail: bstuart@fieldmuseum.org

The University of Illinois at Chicago, Department of Biological Sciences
845 W. Taylor, Chicago, Illinois 60607, USA

The frog fauna of Laos (Lao People's Democratic Republic) is poorly known relative to that of neighboring Thailand, China, and Vietnam. Bourret's (1942) regional monograph remains the major work on the frog fauna of Laos. Stuart (1999) compiled a list of the frog species and the general regions and habitats in which they were known to occur in the country, and Teynié et al. (2004) reported on a collection from southern Laos. Seven new species of frogs from Laos have been recently described based on new and old collections (Inger and Kottelat 1998; Ohler 2003; Bain and Nguyen 2004; Ohler et al. 2004; Stuart and Heatwole 2004; Stuart and Chan-ard 2005; Stuart et al. 2005).

I conducted herpetological fieldwork throughout Laos between February 1998 and December 2000, and specimens were deposited at the Field Museum of Natural History (FMNH). Herein, country and provincial records of 46 species of frogs are reported. Some of the earlier records were listed in Stuart (1999), but voucher numbers and detailed locality information were not provided. Therefore, those records are presented again here with such information, and identifications are corrected where needed. Records reported by Stuart (1999) are treated here as first country records only if other authors have not reported them since.

FAMILY MEGOPHRYIDAE

Brachytarsophrys intermedia. XE KONG PROVINCE, Kaleum District, Xe Sap National Biodiversity Conservation Area: FMNH 258093-096, 16°04'10"N 106°58'45"E, 1200–1300 m elevation, rocky streams in wet evergreen forest, 07–08 July 1999, B. L. Stuart. Males were calling day and night. Three males (FMNH 258093–094, 258096) were calling from under partly submerged rocks or rock crevices in streams, and one male (FMNH 258095) was floating in a stream pool next to a boulder pile at the base of small cascade. One male (FMNH 258094) was in a rocky stream guarding a large clutch of eggs (FMNH 258902) that were adhered to the underside of a partly submerged 1 x 1 m rock adjacent to the back of the calling male. The eggs were uniformly yellow, without a pigmented hemisphere, and 4.5–5.0 mm in diameter. First country record.

Leptobrachium banae. XE KONG PROVINCE, Kaleum District, Xe Sap National Biodiversity Conservation Area, near Houay Alung Stream: FMNH 258079, 16°00'32"N 106°55'31"E, 920–1000 m elevation, on leaf litter in evergreen forest, 30 June 1999, B. L. Stuart. In life, upper iris light blue, limbs with orange crossbars, and flank with scattered orange flecking. First country record.

Leptobrachium chapaense. BOLIKHAMXAY PROVINCE, Khamkeut District, Nape border area: FMNH 258065, 258067–

071, wet evergreen forest, 17–19 March 1997, D. Davenport. In life, upper iris light blue. Reported as *L. pullum* in Stuart (1999). Reported from Bokeo Province (Dubois and Ohler 1998). First provincial record.

Leptobrachium smithi. SAYABOURY PROVINCE, Phiang District, west of Mekong River: FMNH 258091–092, 258097, 258101–106, near 18°54'08"N 101°34'30"E, 250–400 m elevation, disturbed evergreen forest, 01 September 1999, M. Baltzer. VIENTIANE PROVINCE, Xanakham District: FMNH 263263, near 18°07'57"N 101°29'30"E, 300–600 m elevation, gallery evergreen mixed with bamboo and deciduous forest, November 2000, T. Hansel. First country record.

Leptolalax bourreti. PHONGSALY PROVINCE, Phongsaly District, Phou Dendin National Biodiversity Conservation Area: FMNH 258052–056, near Nam Ou River, 22°05'38"N 102°12'50"E, 600 m elevation, on leaf of herbaceous plant, dirt bank, or rock near small rocky streams in hill evergreen forest, 07–11 October 1999, B. L. Stuart and H. F. Heatwole; FMNH 258057, near Nam Khang River, near 22°09'04"N 102°12'19"E, 600 m elevation, on leaf of herbaceous plant 3 m from stream in hill evergreen forest, 14 October 1999, B. L. Stuart and H. F. Heatwole; FMNH 258058, 258060, 258066, confluence of Nam Ou and Houay Han Streams, 22°05'31"N 102°06'19"E, 600–800 m elevation, on rocky bank at edge of swift stream in hill evergreen mixed with bamboo forest, 19 October 1999, B. L. Stuart and H. F. Heatwole; FMNH 258059, 258061–064, Houay Han Stream, near Nam Ou River, near 22°05'31"N 102°06'19"E, 600–800 m elevation, on tree root, rocks, or leaf litter on bank of small rocky stream in hill evergreen forest, 19–21 October 1999, B. L. Stuart and H. F. Heatwole. BOLIKHAMXAY PROVINCE, Khamkeut District, Nape border area: FMNH 258035–045, wet evergreen forest, 15–18 March 1997, D. Davenport. Reported as *L. pelodytoides* (part) in Stuart (1999). First country record.

Leptolalax oshanensis. PHONGSALY PROVINCE, Phongsaly District, Phou Dendin National Biodiversity Conservation Area, near confluence of Nam Ou and Nam Sa Rivers: FMNH 258077, near 22°05'31"N 102°06'19"E, 600 m elevation, under leaf litter in hill evergreen forest, 20 October 1999, B. L. Stuart and H. F. Heatwole. BOLIKHAMXAY PROVINCE, Khamkeut District, Nape border area: FMNH 257989–992, wet evergreen forest, 15–19 March 1997, D. Davenport. KHAMMOUAN PROVINCE, Navang: FMNH 257986–988, 26 February 1997, D. Davenport. Reported as *L. pelodytoides* (part) in Stuart (1999). First country record.

Megophrys major. PHONGSALY PROVINCE, Phongsaly District, Phou Dendin National Biodiversity Conservation Area: FMNH 258571–575, near Nam Ou River, 22°05'38"N 102°12'50"E, 600 m elevation, on mid-stream rock and on rocks and branches along bank of small rocky streams in hill evergreen forest, 07–11 October 1999, B. L. Stuart and H. F. Heatwole; FMNH 258576, near Nam Khang River, near 22°09'04"N 102°12'19"E, 600 m elevation, hill evergreen forest, 12 October 1999, B. L. Stuart and H. F. Heatwole; FMNH 258577, Houay Han Stream, near Nam Ou River, near 22°05'31"N 102°06'19"E, on rock next to 3 x 3 m pool at base of 2-m high waterfall in hill evergreen forest, 600–800 m elevation, 19 October 1999, B. L. Stuart and H. F. Heatwole; FMNH 258578, near Houay Aw Stream, near Nam Ou River, near 22°05'44"N 102°08'10"E, 600–800 m elevation, on sandy bank among boulders 1 m from swift stream in hill evergreen forest, 24 October 1999, B. L. Stuart and H. F. Heatwole. HUAPHAHN PROVINCE, Vieng Tong District, Phou Louey National Biodiversity Conservation Area, Phou Louey Mountain: FMNH 255542, 20°14'N 103°12'E, 1200 m elevation, on rock on bank of swift stream in hill evergreen forest, 03 May 1998, B. L. Stuart. BOLIKHAMXAY PROVINCE, Khamkeut District, Ban Nape border area: FMNH 258539–541, 258543, wet evergreen forest, 17–19 March 1997, D. Davenport. KHAMMOUAN PROVINCE, Nakai District, Nakai-Nam Theun National Biodiversity Conservation Area: FMNH 256440, near Houay Ting Tou Stream, 17°58'N 105°34'E, 700 m elevation, calling from leaf of herbaceous plant 2 m above stream in evergreen forest, 07 November 1998, B. L. Stuart; FMNH 256441, near Houay Duen Stream 17°57'N 105°34'E, 700 m elevation, submerged at rocky bank of stream in evergreen forest, 10 November 1998, B. L. Stuart. XE KONG PROVINCE, Kaleum District, Xe Sap National Biodiversity Conservation Area: FMNH 258545, near Houay Alung Stream, 16°00'32"N 106°55'31"E, 920–1000 m elevation, on leaf litter of forest floor away from water in wet evergreen forest, 30 June 1999, B. L. Stuart; FMNH 258544, 258546, near Houay Batay Stream, 16°01'30"N 106°55'40"E, 780–900 m elevation, on leaf litter bank 5–8 m above small rushing stream in disturbed evergreen forest, 29 June 1999, B. L. Stuart; FMNH 258547–548, near 16°04'10"N 106°58'45"E, 1200 m elevation, under rock ledge and on log next to small rocky stream in wet evergreen forest, 07 July 1999, B. L. Stuart. CHAMPASAK PROVINCE, Pakxong District, Dong Hua Sao National Biodiversity Conservation Area, Bolaven Plateau: FMNH 258549–551, 258553–55, near 15°04'37"N 106°08'15"E, 1000 m elevation, on and under leaf litter in forest away from water, on ground in coffee plantation away from water, and on mid-stream rock of rushing stream in wet evergreen forest with coffee plantation clearings, 11–13 September 1999, B. L. Stuart and H. F. Heatwole; FMNH 258563, 258565–570, near 15°03'55"N 106°13'03"E, 1200 m elevation, on and under leaf litter in forest away from water and on rock bank 1 m from stream in wet evergreen forest, 21–23 September 1999, B. L. Stuart and H. F. Heatwole; FMNH 258556, near 15°02'48"N 106°10'45"E, 400 m elevation, on large boulder 6 m from stream in wet evergreen forest, 18 September 1999, B. L. Stuart and H. F. Heatwole; FMNH 258557–562, near Ban Nongluang Village, near 15°04'07"N 106°12'03"E, 1100 m elevation, 20 September 1999, B. L. Stuart and H. F. Heatwole. Reported as *M. lateralis* in Stuart (1999). First country record.

Megophrys palpebralespinosa. PHONGSALY PROVINCE, Phongsaly District, Phou Dendin National Biodiversity Conservation Area, near Nam Ou River: FMNH 258098–100, 22°05'38"N 102°12'50"E, 600 m elevation, under leaf litter or along rocky streams in hill evergreen forest, 07–09 October 1999, B. L. Stuart and H. F. Heatwole. First country record.

Megophrys parva. PHONGSALY PROVINCE, Phongsaly District, Phou Dendin National Biodiversity Conservation Area, near Houay Aw Stream, tributary of Nam Ou River: FMNH 258578, near 22°05'44"N 102°08'10"E, 600–800 m elevation, on sandy bank among boulders 1 m from swift stream in hill evergreen forest, 24 October 1999, B. L. Stuart and H. F. Heatwole.

HUAPHAHN PROVINCE, Vieng Tong District, Nam Et National Biodiversity Conservation Area, near Houay Louen Stream: FMNH 255543, in leaf litter on stream bank, 30 April 1998, D. Showler. First country record.

Ophryophryne gerti. CHAMPASAK PROVINCE, Pakxong District, Dong Hua Sao National Biodiversity Conservation Area, Bolaven Plateau: FMNH 258564, near 15°03'55"N 106°13'03"E, 1200 m elevation, in shallow water of 1 x 1 m side pool of stream in wet evergreen forest, 22 September 1999, B. L. Stuart and H. F. Heatwole. One paratype from "Huey Sapan, Pak Maat, Mekong, Laos" (Ohler 2003), but this precise locality has not been found (Ohler 2003). First provincial record.

Ophryophryne hansi. BOLIKHAMXAY PROVINCE, Khamkeut District, Nape border area, Nape Stream: FMNH 258001–007, 258072–073, wet evergreen forest, 15–18 March 1997, D. Davenport. KHAMMOUAN PROVINCE, Nakai District, Nakai-Nam Theun National Biodiversity Conservation Area, near Houay Ting Tou Stream: FMNH 256448, 17°57'N 105°34'E, 700 m elevation, on fern growing from rock face 2 m above stream pool in evergreen forest, 09 November 1998, B. L. Stuart. XE KONG PROVINCE, Kaleum District, Xe Sap National Biodiversity Conservation Area: FMNH 258009–010, 258046–051, 16°04'10"N 106°58'45"E, 1100–1300 m elevation, on leaves, logs, rocks, and boulders along small rocky streams and stream pools in wet evergreen forest, 06–09 July 1999, B. L. Stuart; FMNH 258008, near Houay Alung Stream, 16°00'32"N 106°55'31"E, 920–1000 m elevation, on rock ledge 15 cm above small stream in wet evergreen forest, 30 June 1999, B. L. Stuart. Reported as *O. poilani* in Stuart (1999). First country record.

FAMILY BUFONIDAE

Bufo galeatus. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area: FMNH 255315, 255322–325, 17°20'N 105°41'E, 500 m elevation, near pools in temporary stream bed in dry evergreen mixed with deciduous forest, 24–25 February 1998, B. L. Stuart. KHAMMOUAN PROVINCE, Nakai District, Nakai Nam Theun National Biodiversity Conservation Area, near Houay Dreng Stream: FMNH 256442–445, 17°50'N 105°35'E, 600 m elevation, near side pools of stream in wet evergreen forest, 03 December 1998, B. L. Stuart. First country record.

Bufo macrotis. VIENTIANE MUNICIPALITY, Vientiane: FMNH 257916–917, 17°58'41"N 102°39'16"E, 190 m elevation, on road at night during rain, 09 June 1999, B. L. Stuart. CHAMPASAK PROVINCE, Mounlapamok District, Dong Khanthung National Biodiversity Conservation Area, near Xe Lepou River: FMNH 255316–320, near Ban Thakang Village, grassland with deciduous dipterocarp forest, 14°07'N 105°40'E, 60 m elevation, on exposed branches and floating sticks in flooded deciduous dipterocarp forest, 06 July 1998, B. L. Stuart; FMNH 255321, 14°07'N 105°29'E, 60 m elevation, on sandy trail in grassland with deciduous dipterocarp forest and dry evergreen forest, 12 July 1998, B. L. Stuart. First country record.

Bufo melanostictus. PHONGSALY PROVINCE, Phongsaly District, Phou Dendin National Biodiversity Conservation Area, near Nam Khang River on Nam Kaw Stream: FMNH 257948–949, near 22°09'39"N 102°11'07"E, 600 m elevation, on pebble bank 3 m from stream in hill evergreen forest, 15 October 1999, B. L. Stuart and H. F. Heatwole. SAYABOURY PROVINCE, Phiang District, west of Mekong River: FMNH 257945, near 18°54'08"N 101°34'30"E, 250–400 m elevation, disturbed evergreen forest, 01 September 1999, M. Baltzer. BOLIKHAMXAY PROVINCE, Khamkeut District, Lac Xao: FMNH 254555–557, on road at night, near building, and near pond in dry evergreen forest, 01–14 October 1996, D. Davenport and H. F. Heatwole. Reported from throughout Indochina but without specific localities in Laos (Bourret 1942), and in Laos from Vientiane Municipality (Teynié et al. 2004), Khammouan Province (Stuart and Davidson 1999), and Champasak Province (Teynié et al. 2004). First provincial records.

FAMILY MICROHYLIDAE

Kalophrynus interlineatus. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area: FMNH 255124, 17°30'N 105°51'E, 200 m elevation, near pool at entrance of limestone cave in dry evergreen mixed with deciduous forest, 15 February 1998, B. L. Stuart. Reported as *K. pleurostigma* in Stuart (1999). Reported from Champasak Province (Teynié et al. 2004). First provincial record.

Kaloula pulchra. VIENTIANE MUNICIPALITY, Vientiane: FMNH 257912, 17°58'24"N 102°36'57"E, 190 m elevation, on road at night during rain, 09 June 1999, B. L. Stuart. BOLIKHAMXAY PROVINCE, Thaphabat District, Phou Khao Khouay National Biodiversity Conservation Area, Houay Kay River near That Xay Waterfall: FMNH 255129, 18°27'N 103°10'E, 300 m elevation, on rock ledge 1 m above ground 2 m from river, 27 June 1998, B. L. Stuart. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area: FMNH 255127, 17°34'N 105°50'E, 200 m elevation, on bank of flat stream near limestone karst in dry evergreen mixed with deciduous forest, 10 February 1998, B. L. Stuart. Reported from throughout Indochina but without specific localities in Laos (Bourret 1942), and in Laos from Champasak Province (Teynié et al. 2004). First provincial records.

Microhyla berdmorei. PHONGSALY PROVINCE, Phongsaly District, Phou Dendin National Biodiversity Conservation Area: FMNH 257920-923, near Nam Ou River, near 22°05'38"N 102°12'50"E, 600 m elevation, hill evergreen forest, 09–11 October 1999, B. L. Stuart and H. F. Heatwole; FMNH 257924–926, near Nam Khang River, near 22°09'04"N 102°12'19"E, 600 m elevation, hill evergreen forest, 13–14 October 1999, B. L. Stuart and H. F. Heatwole. BOLIKHAMXAY PROVINCE, Khamkeut District, Lac Xao: FMNH 254602–603, 254606–607, 254610–617, 28 September–29 October 1996, D. Davenport and H. F. Heatwole. KHAMMOUAN PROVINCE, Nakai District, Nakai-Nam Theun National Biodiversity Conservation Area: FMNH256446, along Houay Ting Tou Stream, 17°58'N 105°34'E, 700 m elevation, on sand bank of stream in disturbed evergreen forest, 08 November 1998, B. L. Stuart; FMNH 256447, along Houay Duen Stream, 17°57'N 105°34'E, 700 m elevation, on rocky bank of stream in evergreen forest, 10 November 1998, B. L. Stuart. SAVANNAKHET PROVINCE, Tapanthong District, Dong Sithovane Production Forest: FMNH 258078, 16°07'41"N 105°54'53"E, on rocky flats near stream pools, 17 January 2000, R. Boonratana. ATTAPEU PROVINCE, Sanamsai District, Ban

Mai Village, Nong Khe Wetlands: FMNH 262656, 14°42'35"N 106°28'00"E, 100 m elevation, along rocky shoreline of marsh in deciduous forest, 17 September 2000, B. L. Stuart. Reported from Champasak Province (Teynié et al. 2004). First provincial records.

Microhyla butleri. HUAPHAHN PROVINCE, Vieng Tong District, Phou Louey National Biodiversity Conservation Area, near Ban Houay Sa abandoned village: FMNH 255072, 20°13'N 103°15'E, 1000 m elevation, under log at edge of 3 x 4 m buffalo wallow ca. 6 m from stream, 25 April 1998, B. L. Stuart. BOLIKHAMXAY PROVINCE, Khamkeut District, Lac Xao: FMNH 254599, on leaf litter of dry evergreen forest, 06 October 1996, D. Davenport. KHAMMOUAN PROVINCE, Nakai District, Phou Hin Poun National Biodiversity Conservation Area: FMNH 255066–071, 255225, 17°51'N 104°52'E, 220 m elevation, on leaf litter of temporary stream bed in dry evergreen mixed with deciduous forest, 17–20 March 1998, B. L. Stuart and T. Chan-ard. Reported from Champasak Province (Teynié et al. 2004). First provincial records.

Microhyla fissipes. BOLIKHAMXAY PROVINCE, Khamkeut District, Lac Xao: FMNH 254587, 254598, dry evergreen forest, 07 October and 13 November 1996, D. Davenport and H. F. Heatwole. CHAMPASAK PROVINCE, Mounlapamok District, Dong Khanthung National Biodiversity Conservation Area, near Ban Thakang Village: FMNH 255130–131, near Ban Thakang village, on Xe Lepou River, 14°07'N 105°40'E, 60 m elevation, at edge of 2 x 3 m puddle in grassland with deciduous dipterocarp forest, 06 July 1998, B. L. Stuart. Recently resurrected from the synonymy of *M. ornata* by Matsui et al. (2005). Reported as *M. ornata* from "Tra-ninh (Xieng-khouang)" in Xieng Khouang Province (Bourret 1942), Vientiane (Bourret 1942), and Khammouan Province (Stuart and Davidson 1999). First provincial records.

Microhyla heymonsi. HUAPHAHN PROVINCE, Vieng Tong District, Phou Louey National Biodiversity Conservation Area: FMNH 255085–086, near Ban Houay Sa abandoned village, 20°13'N 103°15'E, 1000 m elevation, under log at edge of 3 x 4 m buffalo wallow approximately 6 m from stream, 25 April 1998, B. L. Stuart; FMNH 255087, near Nam Poung River, 20°14'N 103°16'E, 985 m elevation, in marsh in clearing of hill evergreen forest, 28 April 1998, B. L. Stuart. SAYABOURY PROVINCE, Phiang District, west of Mekong River: FMNH 257985, near 18°54'08"N 101°34'30"E, 250–400 m elevation, near village in disturbed evergreen forest, 01 September 1999, M. Baltzer. BOLIKHAMXAY PROVINCE, Khamkeut District, Nape border area: FMNH 257974–983, wet evergreen forest, 15–19 March 1997, D. Davenport. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area: FMNH 255076–081, near Ban Dou Village, 17°31'N 105°49'E, 200 m elevation, on leaf litter in dry stream bed in dry evergreen mixed with deciduous forest, 09 February 1998, B. L. Stuart. CHAMPASAK PROVINCE, Pakxong District, Dong Hua Sao National Biodiversity Conservation Area, Bolaven Plateau: FMNH 257984, near 15°03'55"N 106°13'03"E, 1200 m elevation, under leaf litter in wet evergreen forest, 25 September 1999, B. L. Stuart and H. F. Heatwole. CHAMPASAK PROVINCE, Mounlapamok District, Dong Khanthung National Biodiversity Conservation Area: FMNH 255074-075, near Houay Khiem Stream, 14°08'N 105°22'E, 60 m elevation, on sandy road through grassland with deciduous dipterocarp forest, 20–21 July 1998, B. L. Stuart. First country record.

Microhyla pulchra. KHAMMOUAN PROVINCE, Yommalat District, Bang Vieng Village: FMNH 255090-093, 17°20'N 104°57'E, 200 m elevation, under dry mud of buffalo wallow, 31 March 1998, B. L. Stuart. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area: FMNH 255089, 17°34'N 105°50'E, 200 m elevation, on bank of wide stream in dry evergreen mixed with deciduous forest, 10 February 1998, B. L. Stuart. SAVANNAKHET PROVINCE, Tapanthong District, Dong Sithovane Production Forest: FMNH 257998–999, 16°02'05"N 105°43'22"E, near dirt road, 16 January 2000, R. Boonratana; FMNH 258000, 16°07'40"N 105°54'53"E, on rocky flats near stream pools, 17 January 2000, R. Boonratana. CHAMPASAK PROVINCE, Mounlapamok District, Dong Khanthung National Biodiversity Conservation Area: FMNH 255094–096, 14°09'N 105°39'E, 100 m elevation, on grassy bank of 3 x 10 m buffalo wallow in grassland with deciduous dipterocarp forest, 08 July 1998, B. L. Stuart. CHAMPASAK PROVINCE, Khong District, Ban Sonlavieng Village: FMNH 257993–996, 14°01'56"N 105°54'15"E, 100 m elevation, in rice paddy, 26 January 2000, B. Phommachat. Reported from "N.-Laos: Samneua (Muong-het)" in Huaphanh Province (Bourret 1942). First provincial records.

Micryletta inornata. BOLIKHAMXAY PROVINCE, Khamkeut District, Lac Xao: FMNH 254600–601, dry evergreen forest, 02 October and 10 November 1996, D. Davenport and H. F. Heatwole. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area: FMNH 255120, Phou Khaonok Mountain, 17°23'N 105°45'E, 545 m elevation, on leaf litter in dry evergreen mixed with deciduous forest, 21 February 1998, B. L. Stuart; FMNH 255121, 17°17'N 105°41'E, 240 m elevation, on leaf litter among limestone boulders in dry evergreen mixed with deciduous forest, 27 February 1998, B. L. Stuart; FMNH 255122, 17°20'N 105°41'E, 500 m elevation, on leaf litter at base of tree in dry evergreen mixed with deciduous forest, 26 February 1998, B. L. Stuart; FMNH 255221, 17°30'N 105°51'E, 200 m elevation, under log in deciduous forest, 16 February 1998, B. L. Stuart. KHAMMOUAN PROVINCE, Nakai District, Phou Hin Poun National Biodiversity Conservation Area: FMNH 255123, 17°51'N 104°52'E, 220 m elevation, on leaf litter of temporary stream bed in dry evergreen mixed with deciduous forest, 17 March 1998, B. L. Stuart and T. Chan-ard. Reported as *Microhyla inornata* in Stuart (1999). First country record.

Family Ranidae

Amolops cremnobatus. VIENTIANE MUNICIPALITY, Kasi District, east of Mekong River, near Ban Namon Village: FMNH 258376–377, 19°04'39"N 102°08'44"E, 200–300 m elevation, M. Baltzer, 01 September 1999. BOLIKHAMXAY PROVINCE, Khamkeut District, Ban Nape border area: FMNH 258367–375, on vertical moss-covered rocks in splash zone of large waterfall in wet evergreen forest, 19–20 March 1997, D. Davenport. The type locality is in Khammouan Province (Inger and Kottelat 1998). First provincial records.

Huia nasica. HUAPHAHN PROVINCE, Vieng Tong District, Phou Louey National Biodiversity Conservation Area, Phou Louey Mountain: FMNH 255399, 20°14'N 103°12'E, 1200 m elevation,

on rocky bank of stream in hill evergreen forest, 03 May 1998, B. L. Stuart. BOLIKHAMXAY PROVINCE, Khamkeut District, Ban Nape border area: FMNH 258221, wet evergreen forest, 17 March 1997, D. Davenport. KHAMMOUAN PROVINCE, Nakai District, Nakai-Nam Theun National Biodiversity Conservation Area: FMNH 256470–471, 256491, along Houay Dreng Stream, 17°50'N 105°35'E, 600 m elevation, along small rocky stream in wet evergreen forest, 01–02 December 1998, B. L. Stuart; FMNH 256472–478, 17°58'N 105°34'E, 700 m elevation, on rocks and vegetation along cascading stream in evergreen forest, 06–07 November 1998, B. L. Stuart. FMNH 256470 and 256491 were in amplexus at the bottom of a stream pool under 75 cm of water. The Huaphahn specimen was reported as *Rana montivaga* in Stuart (1999). First country record.

Hoplobatrachus rugulosus. CHAMPASAK PROVINCE, Mounlapamok District, Dong Khanthung National Biodiversity Conservation Area: FMNH 255191, 255200, near Houay Khiem stream, 14°08'N 105°22'E, 60–100 m elevation, on bank of stream and on road in mosaic of dry evergreen forest and grassland with deciduous dipterocarp forest, 19–20 July 1998, B. L. Stuart; FMNH 255192, near Ban Nong Som Hong Village, 105°40'E 14°17'E, 100 m elevation, on sandy road away from water, 25 July 1998, B. L. Stuart; FMNH 255193–194, near Ban Thakang Village on Xe Lapou River, 14°07'N 105° 40'E, 60 m elevation, in road puddle in grassland with deciduous dipterocarp forest, 06 July 1998, B. L. Stuart; FMNH 255197–199, 14°07'N 105°29'E, 60 m elevation, in puddle in grassy area and on mud bank of pond in mosaic of dry evergreen forest and grassland with deciduous dipterocarp forest, 11–13 July 1998, B. L. Stuart. CHAMPASAK PROVINCE, Khong District, Ban Sonlavieng Village: FMNH 258192–193, 14°01'56"N 105°54'15"E, 100 m elevation, in rice paddy, 18 July 1999, B. L. Stuart. Reported from throughout Indochina at low elevations but without specific localities in Laos (Bourret 1942), and in Laos from Khammouan Province (Stuart and Davidson 1999). First provincial record.

Limnonectes gyldenstolpei. VIENTIANE PROVINCE, Xanakham District: FMNH 261874–877, near 18°07'57"N 101°29'30"E, 300–600 m elevation, gallery evergreen mixed with bamboo and deciduous forest, November 2000, T. Hansel. Reported from "Muang Liep, Huey Kan Luang and Pon Pissay in French Laos on the Upper Mekong" (Smith 1922; as *Rana pileata*). Muang Liep is in Sayaboury Province, but I have not found the other localities. First provincial record.

Occidozyga lima. BOLIKHAMXAY PROVINCE, Khamkeut District, Lac Xao, near Lake Nam Bua: FMNH 254657, in grassy puddle at edge of dry evergreen forest, 14 October 1996, D. Davenport and H. F. Heatwole. KHAMMOUAN PROVINCE, Yommalat District, Bang Vieng Village: FMNH 255138, 17°20'N 104°57'E, 200 m elevation, on bank of small stream through rice paddy, 30 March 1998, B. L. Stuart. CHAMPASAK PROVINCE, Mounlapamok District, Dong Khanthung National Biodiversity Conservation Area: FMNH 255136, near Houay Khiem Stream, 14°08'N 105°22'E, 60 m elevation, in flooded grassland with deciduous dipterocarp forest, 20 July 1998, B. L. Stuart; FMNH 255137, near Nong Tum Pond, 14°16'N 105°20'E, 100 m elevation, in 10 x 10 m pond in grassland with deciduous dipterocarp forest, 24 July 1998, B. L. Stuart; FMNH 255139, 14°07'N 105°29'E, 60 m elevation, at edge of 20 x 20 m pond in dry evergreen forest, 11 July 1998, B. L. Stuart. CHAMPASAK PROVINCE, Khong District, Ban Sonlavieng Village: FMNH 258392–408, 14°01'56"N 105°54'15"E, 100 m elevation, in rice paddy, 18 July 1999 and 26 January 2000, B. L. Stuart and B. Phommachat. Reported from "Haut-Laos: Muong Ouneua" in Phongsaly Province (Bourret 1942). First provincial records.

Occidozyga martensii. VIENTIANE PROVINCE, Xanakham District: FMNH 261826, near 18°07'57"N 101°29'30"E, 300–600 m elevation, November 2000, T. Hansel. BOLIKHAMXAY PROVINCE, Khamkeut District, Lac Xao: FMNH 254670, 254681, on path through dipterocarp forest and in elephant footprint in dry evergreen forest, 08 and 29 October 1996, D. Davenport and H. F. Heatwole. ATTAPEU PROVINCE, Sanamsai District, Ban Mai Village, Nong Khe Wetlands: FMNH 261823–825, 14°42'35"N 106°28'00"E, 100 m elevation, along rocky shoreline of marsh in deciduous forest, 17 September 2000, B. L. Stuart. Reported from Khammouan Province (Stuart and Davidson 1999) and Champasak Province (Teynié et al. 2004; as *Phrynoglosssus martensii*). First provincial records.

Rana attigua. CHAMPASAK PROVINCE, Pakxong District, Dong Hua Sao National Biodiversity Conservation Area, Bolaven Plateau: FMNH 258251, 258348–349, near 15°04'37"N 106°08'15"E, 1000 m elevation, on vegetation along stream in wet evergreen forest or on ground in coffee plantation away from water in wet evergreen forest with coffee plantation clearings, 10–13 September 1999, B. L. Stuart and H. F. Heatwole; FMNH 258253–257, 258350, Ban Nongluang Village, near 15°04'07"N 106°12'03"E, 1100 m elevation, 20 September 1999, B. L. Stuart and H. F. Heatwole; FMNH 258264–265, 258258, near 15°03'55"N 106°13'03"E, 1200 m elevation, under leaf litter in wet evergreen forest, 21–23 September 1999, B. L. Stuart and H. F. Heatwole. XE KONG PROVINCE, Kaleum District, Xe Sap National Biodiversity Conservation Area: FMNH 258247, along Houay Alung Stream, 16°00'32"N 106°55'31"E, 920–1000 m elevation, on herbaceous leaf above side pool of large rushing stream in evergreen forest, 30 June 1999, B. L. Stuart; FMNH 258248, near 16°04'10"N 106°58'45"E, 1100–1280 m elevation, on rock 15 cm from small stream in wet evergreen forest, 06 July 1999, B. L. Stuart. First country record.

Rana chapaensis. XIENG KHOUANG PROVINCE, Pek District, Phonsavan Market: FMNH 256531–532, offered for sale alive in food market (probably collected nearby), 12 February 1999, B. L. Stuart. SALAVAN PROVINCE, Samoy District, Xe Sap National Biodiversity Conservation Area, near Ban Bee Hi Village: FMNH 262576–577, 16°08'46"N 106°56'50"E, 1220 m elevation, slow-moving muddy stream with palm trees, 04 March 1999, T. Chanard. First country record.

Rana daorum. HUAPHAHN PROVINCE, Vieng Tong District, Phou Louey National Biodiversity Conservation Area, Phou Louey Mountain: FMNH 255353–355, 20°14'N 103°12'E, 1200 m elevation, along small rocky stream in hill evergreen forest, 02–03 May 1998, B. L. Stuart. First country record.

Rana johnsi. BOLIKHAMXAY PROVINCE, Khamkeut District, Ban Nape border area: FMNH 258278, wet evergreen forest, 19 March 1997, D. Davenport; FMNH 254701–702, floodplain of

Nam Pheo River, 8 km NE of Nape, 2 km SW of Vietnam border, under stones on river floodplain through wet evergreen forest, 13 November 1996, D. Davenport and H. F. Heatwole. KHAMMOUAN PROVINCE, Nakai District, Nakai-Nam Theun National Biodiversity Conservation Area: FMNH 256511, along Houay Duen Stream, 17°57'N 105°34'E, 700 m elevation, on blade of plant 25 cm above rocky stream bank, 1 m from water, 10 November 1998, B. L. Stuart; FMNH 256512–515, along Houay Mae Stream, 17°57'N 105°35'E, 600 m elevation, on stream bank in degraded evergreen forest, 14 November 1998, B. L. Stuart; FMNH 256516, along Houay Dreng Stream, 17°50'N 105°35'E, 600 m elevation, wet evergreen forest 100 m from stream, 03 December 1998, B. L. Stuart. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area: FMNH 255402, 17°20'N 105°41'E, 500 m elevation, on leaf litter near pool in temporary stream bed in dry evergreen mixed with deciduous forest, 25 February 1998, B. L. Stuart. First country record.

Rana lateralis. BOLIKHAMXAY PROVINCE, Khamkeut District, Lac Xao: FMNH 254713, on leaf litter in dry evergreen forest, 04 October 1996, D. Davenport and H. F. Heatwole. CHAMPASAK PROVINCE, Mounlapamok District, Dong Khanthung National Biodiversity Conservation Area: FMNH 255345–346, 14°09'N 105°39'E, 100 m elevation, away from water in grassland with deciduous dipterocarp forest, 08 July 1998, B. L. Stuart: FMNH 255403, near Houay Khiem Stream, 14°08'N 105°22'E, 60 m elevation, 100 m from pond on sandy road through grassland with deciduous dipterocarp forest, 21 July 1998, B. L. Stuart. First country record.

Rana maosonensis. BOLIKHAMXAY PROVINCE, Khamkeut District, Ban Nape border area: FMNH 258474–483, wet evergreen forest, 14–19 March 1997, D. Davenport. KHAMMOUAN PROVINCE, Nakai District, Nakai-Nam Theun National Biodiversity Conservation Area: FMNH 256517–518, along Houay Dreng Stream, 17°50'N 105°35'E, 600 m elevation, on rocky bank of stream in wet evergreen forest, 01 December 1998, B. L. Stuart; FMNH 256519–522, along Houay Ting Tou Stream, 17°58'N 105°34'E, 700 m elevation, on rocky or sandy bank of stream in evergreen forest, 06–09 November 1998, B. L. Stuart; FMNH 256523, along Houay Mae Stream, 17°57'N 105°35'E, 600 m elevation, on herbaceous leaf 0.5 m over stream in degraded evergreen forest, 14 November 1998, B. L. Stuart; FMNH 256524, along Houay Balong Stream, 17°56'N 105°34'E, 600 m elevation, on leaf litter at edge of dry stream bed in evergreen forest, 16 November 1998, B. L. Stuart. First country record.

Rana taipehensis. KHAMMOUAN PROVINCE, Nakai District, Phou Hin Poun National Biodiversity Conservation Area: FMNH 255205, 17°51'N 104°52'E, 220 m elevation, on mud bank of small pond in grassy marsh, 19 March 1998, B. L. Stuart and T. Chanard. Reported from Champasak Province (Teynié et al. 2004). First provincial record.

Family Rhacophoridae

Chirixalus doriae. HUAPHAHN PROVINCE, Vieng Tong District, Phou Louey National Biodiversity Conservation Area, near Nam Poung River: FMNH 255213–216, 20°14'N 103°16'E, 985 m elevation, calling from blades of grass above marsh fed by small stream in clearing of hill evergreen forest, 28 April 1998, B. L. Stuart. SAYABOURY PROVINCE, Phiang District, west of Mekong River: FMNH 257937, near 18°54'08"N 101°34'30"E, 250–400 m elevation, disturbed evergreen forest, 01 September 1999, M. Baltzer. Reported from Champasak Province (Teynié et al. 2004). First provincial record.

Chirixalus nongkhorensis. VIENTIANE PROVINCE, Phou Panang Hill Range: FMNH 263102–107, near 18°04'19"N 102°26'46"E, 300 m elevation, in bamboo near large puddle in trail through disturbed forest mixed with scrub and bamboo, 12 September 2000, B. L. Stuart and T. Hansel. VIENTIANE MUNICIPALITY, near Ban Danxang Village: FMNH 257892–894, 257898, 18°05'27"N 102°40'02"E, 190 m elevation, on vegetation above grassy marsh next to road, 13 June 1999, B. L. Stuart and D. Davenport. Reported from Champasak Province (Teynié et al. 2004). First provincial record.

Chirixalus vittatus. VIENTIANE MUNICIPALITY, near Ban Danxang Village: FMNH 257895–897, 18°05'27"N 102°40'02"E, 190 m elevation, on vegetation above grassy marsh next to road, 13 June 1999, B. L. Stuart and D. Davenport. HUAPHAHN PROVINCE, Vieng Tong District, Phou Louey National Biodiversity Conservation Area, near Nam Poung River: FMNH 255217, 20°14'N 103°16'E, 985 m elevation, calling from blade of grass above marsh fed by small stream in clearing of hill evergreen forest, 28 April 1998, B. L. Stuart. First country record.

Philautus parvulus. XE KONG PROVINCE, Kaleum District, Xe Sap National Biodiversity Conservation Area: FMNH 257938–941, near 16°04'10"N 106°58'45"E, 1200–1300 m elevation, calling from leaves of herbaceous plants or tree trunk 1–2.5 m above ground in wet evergreen forest, 07–08 July 1999, B. L. Stuart. First country record.

Rhacophorus bipunctatus. SAYABOURY PROVINCE, Phiang District, west of Mekong River: FMNH 257899, near 18°54'08"N 101°34'30"E, 250–400 m elevation, disturbed evergreen forest, 01 September 1999, M. Baltzer. First country record.

Rhacophorus calcaneus. XE KONG PROVINCE, Kaleum District, Xe Sap National Biodiversity Conservation Area: FMNH 257905–907, 257932-933, near 16°04'10"N 106°58'45"E, 1200–1300 m elevation, on leaves and branches of bushes and tree over rocky streams in wet evergreen forest, 08 July 1999, B. L. Stuart. First country record.

Rhacophorus dennysi. KHAMMOUAN PROVINCE, Nakai District, Nakai-Nam Theun National Biodiversity Conservation Area, Houay Mae Stream: FMNH 256449–450, 17°57'N 105°35'E, 600 m elevation, on herbaceous plants over stream in degraded evergreen forest, 13–14 November 1998, B. L. Stuart. Reported as *Polypedates feae* in Stuart (1999). First country record.

Rhacophorus feae. PHONGSALY PROVINCE, Phongsaly District, Phou Dendin National Biodiversity Conservation Area, Nam Sa Stream, near confluence of Nam Ou and Nam Sa Rivers: FMNH 257910, near 22°05'31"N 102°06'19"E, 600 m elevation, on 30 cm diameter mid-stream rock in 2 m wide swift rocky stream in hill evergreen forest, 20 October 1999, B. L. Stuart and H. F. Heatwole. First country record.

Rhacophorus orlovi. KHAMMOUAN PROVINCE, Nakai Dis-

trict, Nakai-Nam Theun National Biodiversity Conservation Area: FMNH 256455–457, along Houay Dreng Stream, 17°50'N 105°35'E, 600 m elevation, on rock and vegetation near stream in wet evergreen forest, 01–02 December 1998, B. L. Stuart; FMNH 256458, along Houay Ting Tou Stream, 17°58'N 105°34'E, 700 m elevation, on tree twig 5 m above waterfall in evergreen forest, 06 November 1998, B. L. Stuart; FMNH 256459–461, along Houay Deun Stream, 17°57'N 105°34'E, 700 m elevation, on vegetation in evergreen forest, 11–12 November 1998, B. L. Stuart; FMNH 256462–465, along Houay Dreng Stream, 17°50'N 105°35'E, 600 m elevation, on rock face or vegetation along stream in wet evergreen forest, 03–05 December 1998, B. L. Stuart. Reported as *R. calcaneus* in Stuart (1999). First country record.

Rhacophorus reinwardtii. HUAPHAHN PROVINCE, Vieng Tong District, Phou Louey National Biodiversity Conservation Area, near Nam Poung River: FMNH 255305, 20°14'N 103°16'E, 985 m elevation, on branch 3 m above marsh fed by small stream in clearing of hill evergreen forest, 27 April 1998, B. L. Stuart. SAYABOURY PROVINCE, Phiang District, west of Mekong River: FMNH 257901, near 18°54'08"N 101°34'30"E, 250–400 m elevation, disturbed evergreen forest, 01 September 1999, M. Baltzer. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area, Phou Khaonok Mountain: FMNH 255304, 17°23'N 105°45'E, 545 m elevation, in puddle on forest floor in dry evergreen mixed with deciduous forest, 19 February 1998, B. L. Stuart. First country record.

Theloderma asperum. VIENTIANE PROVINCE, Xanakham District: FMNH 261897, near 18°07'57"N 101°29'30"E, 300–600 m elevation, November 2000, T. Hansel. KHAMMOUAN PROVINCE, Boualapha District, Hin Nam No National Biodiversity Conservation Area: FMNH 255379, 17°20'N 105°41'E, 500 m elevation, on leaf 25 cm above ground along temporary stream bed in dry evergreen mixed with deciduous forest, 23 February 1998, B. L. Stuart. Reported as *Philautus asperrimus* in Stuart (1999). First country record.

Acknowledgments.—The opportunity to work in Laos was made possible by the Wildlife Conservation Society / Division of Forest Resource Conservation Cooperative Program. The Ministry of Agriculture and Forestry, Vientiane, permitted export of specimens to the Field Museum. M. Hedemark, A. Johnson, W. Robichaud, and T. Hansel greatly facilitated work in Laos. H. F. Heatwole and B. Thaovanseng assisted with fieldwork. M. Baltzer, R. Boonratana, T. Chan-ard, D. Davenport, T. Hansel, H. F. Heatwole, B. Phommachat, and D. Showler collected specimens and donated them to the author or the Field Museum. H. Voris, A. Resetar, J. Ladonski, and J. Mui facilitated examining specimens at the Field Museum. Collecting and handling of specimens in the field was in accordance with The Institutional Animal Care and Use Committee of the Field Museum (protocol no. FMNH 02-3). R. Inger shared his taxonomic opinions and critically reviewed this manuscript. Financial support was provided by The John D. and Catherine T. MacArthur Foundation, the National Geographic Society (grant no. 6247-98 with H. Heatwole), and the Wildlife Conservation Society.

Venezuela is considered the ninth most diverse country on earth in reptile diversity (Aguilera et al. 2003) but, as in all tropical countries, much research remains to be done. Venezuela is also one of the most diverse countries with respect to bioregions, having seven (Barrio-Amorós 1998), one of which is the Andes, which in Venezuela reach their northernmost extent. The Venezuelan Andes are approximately 450 km long by 80 km wide in a northeasterly direction, with many peaks reaching almost 5000 m.

Herpetological investigation in this area began in the 19th century, and has continued slowly to the present day. The Venezuelan Andes are in general considered depauperate, especially compared with their southern counterpart in Colombia, which may harbor the most diverse herpetofauna on earth (particularly with respect to amphibians), and is not yet completely studied. The Venezuelan Andes consist of three main ranges (four if the Coastal Range is considered part of the Andes, see Duellman 1999). The principal one is called the Cordillera de Mérida, and is the branch going northeast from the Cordillera Oriental de Colombia. A small part of the Cordillera Oriental de Colombia is also present in Venezuela, where it is called the Tamá Massif. The last range is the Serranía de Perijá, another branch of the Cordillera Oriental which extends northwards. Its watershed constitutes the political border between Venezuela and Colombia. Neither of these two last ranges of the Venezuelan Andes are, however, treated in this book; despite its all inclusive title, the authors considered only the Cordillera de Mérida. Only very briefly, in Appendix II (Registros complementarios de la Sierra de Perijá, el Macizo de Tamá y de bajas elevaciones: "Complemetary records form Sierra de Perijá, Tamá Massif, and lowlands") are some additional species from these areas commented upon.

The book starts with a general physiographic map of northwestern Venezuela and northeastern Colombia. This is followed by a prologue by J. Celsa Señaris, and a presentation by the authors. The introduction discusses the Reptilia as a class, with some generic details. There the authors explain that only reptiles occurring above 1000 m are considered Andean, and thus, treated in the book. Thus, the Andean foothills, with canyons, deep creeks, waterfalls, and other typically montane habitats are excluded. To us, a crystalline, rocky stream, at even 200 m, surrounded by hills and covered by lush forest, where it is possible to find such Andean elements as the dendrobatid frog *Mannophryne collaris*, is indeed part of the Andes, but this definition is up to each author. As a result of this restrictive definition used in the book, many species that are known to inhabit the Andes are not represented in the book. However, strangely, some species that are only known from below 1000 m in the Andes have their own account, like *Hemidactylus palaichthus*, *Bachia heteropa*, *Ameiva ameiva*, and *Liophis reginae zweifeli*.

Next follows a chapter on ecological units of the Andes, by M. Ataroff and L. Sarmiento, which explains the situation of the area, provides a brief geological history, and formally presents the different ecological units, such as humid submontane forest, dry montane forest, cloud forest, Páramos, dry evergreen montane forest, and thorny shrub. Thereafter follows the section containing the species accounts, beginning with Amphisbaenia and Sauria. The use of dichotomous keys is explained and the accounts follows in the familial order: Amphisbaenidae, Gekkonidae, Iguanidae (we are not sure if they regard Iguanidae in the same sense as Schulte et al. (2003), as they do not recognize the families Polychrotidae and Corytophanidae (sensu Frost et al. 2001); when alternative classifications are in use the authors should justify their usages), Gymnophthalmidae, Teiidae and Scincidae. Snakes follow, in the order: Boidae, Colubridae, Anomalepididae, Leptotyphlopidae, Elapidae, and Viperidae. A very short literature section of just 37 titles, without any link to the principal text, but rather chosen subjectively as the best references for Andean reptiles, is given. Finally, there are three appendices: one on snake venoms and their treatment (very basic and obsolete), with no mention of the particular venomous species that can be a problem in the Andes!; the above mentioned appendix II on complementary species form Perijá, Tamá and the lowlands (we will treat this below); and a short glossary of technical terminology.

We found a variety of inconsistencies in the species accounts. Treating *Anolis jacare*, the authors say that it is known from Colombia; this is possible, but we are not aware of any published records. They may be refering to specimens found in the Tamá Massif and earlier considered to be *Phenacosaurus nicefori* (La

Marca 1995). Information on color change and altitudinal range in this taxon is also lacking. When treating *Polychrus marmoratus*, the text claims that its change of color is in consonance with the color of the substratum, which obviously is false. The Andean Chamaleon (*Polychrus* sp.) cannot change the color to match its substrate, but rather does so in relation to emotional state, from the original emerald green to dark brown or gray.

In the introductory text to the family Gymnophthalmidae three genera are mentioned, while in the account and key there are four (*Anadia*, *Bachia*, *Gymnophthalmus* and *Proctoporus*). *Bachia heteropa* does not live exclusively in the Sierra de Perijá and Cordillera Oriental de Colombia; Dixon (1973) reported it from Grenada Island, Trinidad and Tobago, and from the northern Venezuelan coast to the Andean Piedmont. *Proctoporus inanis* (Doan and Schargel 2003) is a species from 1450 m in the Cordillera de Mérida, clearly described and stated to be an Andean species. However, the authors treated this species with only a short comment. *Ameiva provitaae* (sic!) is a typical case of nomenclatural confusion. The first use of the name was in Rodríguez and Rojas-Suárez (1995), as *A. provitai* sp. nov., and a beautiful color drawing accompanied the text. Thus the authors should be Rodríguez and Rojas-Suárez (1995) and not García-Pérez (1995). La Marca and Soriano incorrectly spell the specific epithet *provitaae* and *provitae*. In any case, further investigations must be done in comparison with *A. bifrontata*.

A more extended comment on the *Cnemidophorus lemniscatus* complex, especially about the apparently parthenogenetic Andean populations is lacking and would have been appropriate. We do not understand why the authors state that *Atractus univittatus* is similar to *A. badius*, as the two have proved to be quite different (see Hoogmoed 1980; Starace 2000).

The real local name for *Chironius monticola* in the Andes is "perica." The names presented in this book (lora, verdegallo, machete) are perhaps applicable in other regions or to other green snakes. The authors claim that the type locality of *Dipsas latifrontalis* is the only record known from Venezuela (Aricagua, Mérida state, Venezuelan Andes), although their close collaborators recently published several new localities (Manzanilla et al. 2001) and Fig. 46 shows a specimen of *D. "latifrontalis"* from Cerro Platillón, Guarico (central coastal range). More investigation is needed to clarify the taxonomic status of this snake. We do not know any reference to a *Drymarchon melanurus* of 4 m. The record for the species is 2950 mm (Duellman 1960). If such a reference does exist, it would be valuable to cite it explicitly.

The key for *Erythrolampus* is wrong as the term "triad" is used improperly. A triad-type coloration consists of set of three black rings separated by white-yellow, usually narrower, rings; each triad is separated from the following by a red band (Roze 1996). Both species of *Erytholampus* in the Andes lack triads, and while *E. pseudocorallus* has black single rings surrounded by narrow white rings and separated from the next white-black-white set by a wide red band, *E. bizona* has the contrary coloration, white single rings surrounded by black narrow rings and equally separated from the next set by a wide red band (Roze 1966; see pictures in Campbell and Lamar (2004) and Murphy (1997), for example). The *E. "bizona"* photographed by them is, in fact, an *E. pseudocorallus*.

In the generic information about *Imantodes*, the authors say that there is only one species in Venezuela (*I. cenchoa*); they must not be aware of the citation of *I. lentiferus* by McDiarmid and Paolillo (1988) from Neblina, and by Donnelly and Myers (1991) from Guaiquinima. Contrary to what the authors state, *Lampropeltis triangulum andesiana* (as all species in the genus) are aglyphous snakes, not opistoglyphous (e.g., Williams 1988). On the other hand, the authors neglect to mention that *Liophis* is capable of causing severe envenomations (e.g., Barrio-Amorós 2003 for a case or an envenomation by *Liophis poecilogyrus* in Venezuela; Salomão et al. 2003 and Santos Costa and Di Bernardo 2001 about envenomation by *L. miliaris* in Brazil), stating that *Liophis* is unable to bite. Not to mention a subject so important in a popular book, addressed to people who could be attracted to handling snakes (including children), shows a grave lack of judgement.

The key for *Liophis* is useless; the dorsolateral line in the posterior part of the body mentioned is present in *L. melanotus* (depending how one defines this character) and is not present in *zweifeli* (not the contrary, as stated); one of the important characters to separate species is the immaculate venter of females, but they do not specify how to distinguish between sexes! Although the authors state that *L. reginae zweifeli* can be present at 1000 m, there are no published references to support this.

Later the authors state that there is no information about feeding habits of the species in the genus *Oxyrhopus*. However, Cunha and Nascimento (1993), Duellman (1978) and Murphy (1997), among others, report lizards and small mammals in the diet of snakes of this genus.

Regarding *Liotyphlops albirostris*, in the text the authors say (our translation): "The aspect of this animal is very similar to the previous species". The previous species in the book is *Tantilla semicincta*, a species with no similarities to *L. albirostris*. Perhaps "the next" species, which is *Leptothyphlops affinis*, was intended.

They also seem to defend the old interpretation of not accepting the genus *Leptomicrurus* (see a modern view in Campbell and Lamar 2004). In another coral snake account they state that *Micrurus mipartitus anomalus* ranges in altitude from 500 to 2000 m, although Barrio-Amorós and Calcaño (2003) previously reported three specimens from 250 m asl.

Bothrops asper just reaches central Mexico, not northern, as the authors state (Campbell and Lamar 2004). Lastly, a surprising species to comment on is *Crotalus maricelae*, which was synonymized with *C. durissus cumanensis* by the first author and collaborators recently (Esqueda et al. 2001); furthermore, in the introductory text about the genus *Crotalus*, the authors say that there is only one species of rattlesnake in South America; thus, we don't understand why they recognize the specific status of a "subspecies" that hwas already be to relegated to synonymy. We note the absence of at least three species: *Leptophis ahaetulla*, a species known to inhabit both slopes of the Andes, up to 1400 m, *Thamnodyastes* sp, which occurs in the Lagunillas area (about 1000 m) and *Typhlops reticulatus*, known from the area of La Azulita, at 1400 m. *Norops biporcatus*, mentioned from the Andes of Táchira and Sierra de Perijá (Williams 1966), and recently reported from the Cordillera de Mérida (Rivas and Barrio-Amorós 2003), was not even mentioned in the lowland section.

In several places the authors repeatedly state that data on reproduction do not exist for some species, such as *Leptodeira annulata ashmeadi*, *Liophis reginae zweifeli*, *Masticophis mentovarius suborbitalis*, *Ninia atrata*, *Tantilla melanocephala* and *Epicrates*

maurus, even though that information (hatchling periods and reproduction in captivity) is well known in the literature for Venezuelan populations of these species (Battiston 1996; Silva and Valdez 1989; Muñoz et al 1997), and for others species outside the country (e.g., Censky and McCoy [1988] for *Oxybelis aeneus* and Savage [2002] for *Gonatodes albogularis*).

A book about Andean reptiles would be much more useful if altitudinal ranges for all species are provided (with references to vouchers). A last incongruence we found is the photo of an *Ameiva a. ameiva* from Suriname, although this subspecies is very abundant in many parts of Venezuela. Although the use of photos of extralimital specimens of rare or difficult to find animals is understandable, it is strange that a local guide would not use photos of common species from the area covered.

After all these errors and evidence of misinformation (we could be even more critical!) we doubt that this book accomplishes its aims. Perhaps it is a good introduction for non- professionals, students and the general public, but it is of almost no interest for professionals. In some cases, the authors give some advice about captive feeding, and almost always animals (especially lizards) are fed with *Tenebrio mollitor* larvae, which are known to be a very poor food source.

A major highlight (perhaps the only original highlight) of the book are the pictures, some of very good quality, others not so good, but enough for a visual recognition. We think that a price of about US $35 (plus shipping) is not justified, given the end product. In the future, if these authors want to work on other projects, we suggest that they acknowledge and incorporate a good deal more of the relevant information available in the literature.

The Honduran department of Islas de la Bahía consists of two groups of islands—the Bay Islands (258 km^2) and Cayos Cochinos (2.28 km^2), both of which lie just north of the northern coast of Honduras. The authors of *Amphibians and Reptiles of the Bay Islands and Cayos Cochinos, Honduras* (hereafter abbreviated as BICC) discuss 55 species, of which 12 are endemic to the islands. The main goal of the book is to increase local understanding and awareness about the ecological value of the amphibians and reptiles that occur on the islands. Written in the style of a field guide, the authors explain that, "the descriptions we provide are as untechnical as possible" to allow lay readers to understand and use the book to identify species. Because tourism, development, and the human population are increasing on the islands, all of the endemic species are potentially threatened with extinction. The authors bring decades of expertise with the Honduran herpetofauna (e.g., McCranie and Wilson 2002) to an informative and well-illustrated book that showcases the beauty of the animals with a simultaneous plea for measures to conserve them.

Following a brief foreword by John Meyer, who accompanied Larry David Wilson on his first trip to the Bay Islands in 1967, the book begins with two brief (1–2 pages) Introduction and Materials and Methods sections. These sections are followed by 18 pages of brief descriptions of the islands (with excellent maps), climate, habitats, and very interesting social history. Archaeological sites suggest the islands were first inhabited in pre-Columbian times, and subsequent occupants included Columbus (1502), slave-raiding Spaniards (1516), French, English and Dutch raiders (starting in 1536), British pirates (ca. 1640), British military (1742), and 4000 "Black Caribs" (marooned in 1797) whose English-speaking descendants live on the islands to this day. In 1872, the Islas de la Bahía officially became a department of Honduras, but many residents continued to claim British nationality as recently as 1955.

A six-page section with two tables entitled "The Herpetofauna" summarizes the taxonomic and geographic composition of the 55 species. The following 136 pages include general information for classes, orders and families, keys to major groups (e.g., lizards), and species accounts for the herpetofauna, including seven anurans, one crocodile, five turtles (of which three are marine), 23 lizards (of which seven are endemic), and 19 snakes (of which five are endemic). The keys utilize excellent line drawings and photographs to illustrate specific morphological features used for identifications. Because the University of Kansas collection has numerous specimens from Islas de la Bahía (many collected by Larry David Wilson), I was able to successfully test the keys with the following 25 species: *Hyla microcephala, Smilisca baudinii, Leptodactylus melanonotus, Rana berlandieri, Kinosternon leucostomum, Phyllodactylus palmeus, Sphaerodactylus millepunctatus, S. rosaurae, Anolis allisoni, Norops sagrei, N. lemurinus, Basiliscus vittatus, Ctenosaura oedirhina, C. similis, Gymnophthalmus speciosus, Cnemidophorus lemniscatus, Leptotyphlops goudotii, Boa constrictor, Coniophanes bipunctatus, C. imperialis, Mastigodryas melanolomus, Oxybelis wilsoni, Pseudelaphe flavirufa, Tretanorhinus nigroluteus,* and *Micrurus ruatanus.*

Each species account is 1–2 pages long and includes subheadings for common names, description, similar species, general geographic distribution, distribution on Las Islas de la Bahía, natural history comments, and remarks. The descriptions are one paragraph in length, and include sufficient detail (e.g., modal webbing formulas and scale counts) to be useful to professional herpetologists. The natural history comments involve observations of breeding, diet, predation, and habitat preference from Islas de la Bahía, and the remarks sections include comments about introductions and exploitation by humans, recent taxonomic changes, and local myths—my personal favorite is that *Micrurus ruatanus* will become venomous only after eating toads. Although they are not necessarily incorrect, two taxonomic recognitions in the species accounts require some comments. First, on pg. 138, no citation is provided for the recent recognition of *Drymarchon melanurus,* but it is consistent with taxonomic changes suggested by Wüster et al. (2001). Based on a Principal Components Analysis that included eight Central American specimens (one from Honduras), these authors recognized *D. corais melanurus* as a distinct species. This change was not recognized by Köhler (2003). Second, Dixon and Tipton (2004) recognized *Mastigodryas* as the valid genus for all species of *Dryadophis,* but this change was not incorporated into the BICC; perhaps the authors do not agree with this change, or the paper was not published in time to be incorporated into the book.

The species accounts are followed by several short sections (2–6 pages each) that explore the geographic distribution, habitat preference, conservation status, and future of the islands' herpetofauna. The first section, entitled Ecological Distribution and Relation-

ships of the Herpetofauna, includes a table that lists each species with respect to the following habitats: hardwood forest, pine forest, mangrove forest, coconut groves, ironshore formation, swamps and marshes, estuaries, marine, and urban. A second table uses a Coefficient of Habitat Resemblance (CHR) to compare these major habitats. In the section on Biogeographic Relationships and Significance, a third table is used to compare Coefficients of Biogeographic Resemblance (CBR) among the Bay Islands, Cayos Cochinos, and mainland Honduras. The authors do a good job of discussing trends in similarity among the islands and mainland Honduras, although some biologists might question whether other variables such as the target area effect, rescue effect, and small island effect could also influence island diversity and endemism (Brown and Lomolino 1998). In this same section, the authors point out a close affinity to mainland Honduras in their discussion of the "closest relationships" of the 12 endemic species of the islands, but at least some of these hypotheses have not been subjected to a modern phylogenetic analysis and statements that suggest sister relationships should be interpreted with caution. In the next section on Conservation Status, the authors use the environmental vulnerability score of Wilson and McCranie (2004) to categorize each species as low, medium, or high vulnerability. Their results are mostly consistent with threat classifications of the Global Amphibian Assessment (IUCN et al. 2004) and IUCN Red List for Honduras (IUCN 2004). It was alarming to see that all 12 endemic reptile species were listed in BICC as "high vulnerability," a fact that is made more troubling by the lack of management plans, personnel, and research in most protected areas of the islands. An additional high-vulnerability species, *Ctenosaura melanosterna,* has a limited distribution on mainland Honduras. The Conservation Efforts section describes the formidable challenges faced by proponents of functioning protected areas, although some private landowners have managed to preserve crucial hardwood forest habitats. Two sections entitled Conservation Project Utila Iguana and Cayos Cochinos Biological Reserve explain conservation efforts to protect *Ctenosaura bakeri* and the Cayos Cochinos archipelago, respectively. The last section on the future of the herpetofauna involves a sobering discussion of unchecked human population growth on the islands and Honduras as a whole, and the inevitable effects on natural habitats and the animals that need them to survive. Tourism, land speculation, and transmigration from mainland Honduras are putting increasing pressure on existing protected areas. The ten-page glossary preceding the index is an excellent source for explanations of terms that may be unfamiliar to non-biologists. All citations in the 14-page index were cross-referenced to the text.

My overall impression of the book is very positive. However, I would be remiss if I didn't mention a few minor problems and errors. Several of the photographs are fuzzy, accompanied by captions in colors that make them difficult to read, and the color correction is off in some places, resulting in a dark bluish hue. I noticed some color ink smudging on the text and edges of some photos on my copy. On page 128, pythons are listed as members of the family Boidae. Although the authors do not provide a citation, this view is shared by Pough et al. (2004), who considered Phythoninae as a subfamily of Boidae. However, the BICC authors list ten genera (41 species) for Boidae and cite McDiarmid et al. (1999), who considered Boidae (8 genera, 41 species) and Pythonidae (8 genera, 26 species) as separate families. Grammatical errors and typos were difficult to find, but I noticed a few: pg. 5: "The group consist of two major islands…"; pg. 15: "without monuments, are almost always are found on"; pg. 105: "*Norops lemurinus* a diurnal species…"; lower caption on pg. 81 says *S. millipunctatus* instead of *S. millepunctatus*; and pg. 165 "swamps and marches." In Table 4, I believe the N symbol should be Coefficient of Habitat Resemblance (not Coefficient of Biogeographic Resemblance) to make it consistent with the table legend. However, the CHR is based on the CBR formula.

These minor problems aside, *Amphibians and Reptiles of the Bay Islands and Cayos Cochinos, Honduras* is reasonably priced for the excellent information and wonderful illustrations (over 200 color photos). The sturdy binding and small size (6.25×9.25 in) make it ideal for use in the field. This book will make a fine addition to the libraries of herpetologists interested in Central America and island biogeography. With luck, the book will generate renewed interest in conserving the Bay Islands, which are in need of urgent protection if their endemic species are to survive.

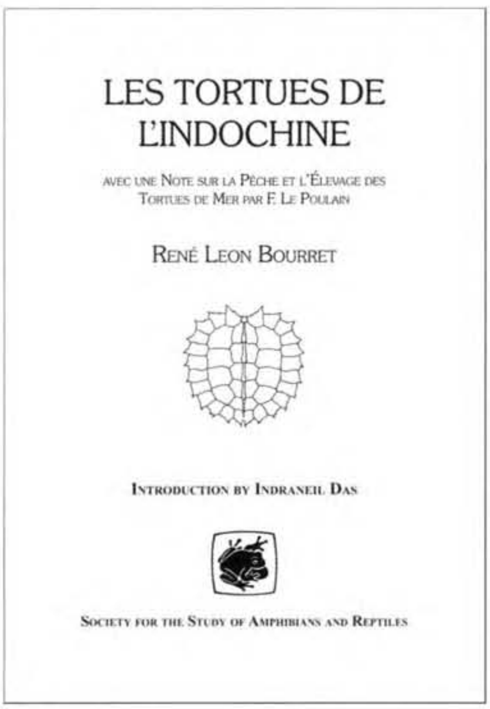
Berkeley, California 94720, USA
e-mail: chuck.crumly@ucpress.edu



By the standards of today, Bourret's book is odd. It might have been odd even when it was originally published over 60 years ago. And yet there is much to recommend the book. Furthermore, because of the crisis now facing the turtles of Southeast Asia, it is especially appropriate that it is reprinted now. The well-intentioned description of new species that are now known to be hybrids provides another rationale for reprinting Bourret's idiosyncratic volume (Parham et al. 2001; Dalton 2003).

What makes this book odd? Most obvious is its organization, beginning with the position of the table of contents at the end of the book. Strange choices and redundancy provide the reader with all the different ways that information on turtles could be organized. Thus, when identification keys could be provide in one form, Bourret provided keys in at least five different contexts – overkill, but still useful. This redundancy would be eliminated today.

The first half of the volume is a review of the turtle fauna of southeastern Asia. The historical introduction is a mostly chronological recitation of names from relevant sources. The literature section for the entire work appears next. The third chapter is a morphological description of turtles customized by reference to the particular turtles under consideration. More on skulls and limbs is included than in most other studies of this vintage. Next, Bourret included a short chapter that today would be entitled "Distribution." This peculiar chapter starts with description in outline form appended by three tables differently describing the distribution of the same species. Another table summarizes the regional composition of the fauna. A tabulation of the altitudinal distribution of turtles in northern and southern Indochina ends the chapter. Bourret ends the first section with dichotomous keys. Separate keys are provided for external characters, heads and limbs, carapaces, plastra, and skulls.

The second major section of the book is arranged species by species. All the accounts are numbered but the system of numbering is hard to discern and on the surface seems both inconsistent and unnecessary. The accounts themselves are loaded with information that is, to this day, very useful. Although museum specimen numbers are lacking, Bourret often provides locality information on the specimens he examined and identifies the institution from whence they came. Each account includes a synonymy, a description, measurements taken (usually from a specimen with a known locality), and information on the location of the type(s) and other specimens figured or referenced by earlier authors. A plate was provided for all species including line drawings of the animal in life, the plastron with and without scutes, the dorsum of the manus, a dorsal and lateral view of the head, a lateral view of the skull and mandible, a ventral view of the cranium, and a dorsal view of the carapace without scutes. Scale bars are provided for the shell drawings, but not for other figures. A dotted line indicates the position of the orbits in the drawings of the ventral cranium.

A short note by Poulain on sea turtles is appended to Bourret's main work, followed by a systematic index, a list of figures and, finally – I said the book was odd, a table of contents. I have taken more trouble than usual to describe the contents of this volume even though the strangeness of the book is only partly revealed in description. The introduction by Das indulges in some of the same description, but in a gentlemanly way, he avoids calling Bourret's book strange. Das has kindly included a table that provides current names for all the names used by Bourret. I hope I am right in noting that Das and I share an admiration for what Bourret did.

Critically speaking, this book could be significantly shorter if various redundancies were omitted and if the data were reported in a more economical layout. But the book would lose its unique qualities and some of its quaint charm (which I believe it had the day it was published). Even some of its scientific importance would have been dissipated if it had been a bit more critically crafted. This book is so useful partly and precisely because it is an anachronism. It is for this reason that the SSAR should be congratulated and the sponsors and patron thanked for bringing Bourret's work to a 21[st] century audience. It will benefit all those interested in the turtles of Southeast Asia to obtain and refer to Bourett's odd book.

PUBLICATIONS RECEIVED

A Field Guide to Amphibians and Reptiles of Maricopa County, by Thomas C. Brennan and Andrew T. Holycross. 2005. Arizona Game and Fish Department, Phoenix, Arizona (www.azgfd.gov/_e/publications.shtml). iv + 68 pp. Softcover. US $5.00. ISBN 0-917563-52-2.

This slender guide provides a concise introduction to the herpetofauna of Maricopa County, the south central Arizona county that includes the city of Phoenix. The county is dominated by Sonoran Desertscrub communities, but also includes montane chaparral and woodlands. The fauna includes 79 native species (14 anurans, 1 salamander, 2 chelonians and 31 species each of lizards and snakes) as well as several introduced forms—surely one of the richest herpetofaunas of any American county. Among these are seven species of rattlesnakes, the Sonoran Coralsnake, and the Gila Monster. Each species is illustrated by a good quality portrait photograph (or several photos in the case of markedly poltypic species or those with distinctive juvenile patterns) and is accompanied by a single paragraph of text (with information on size, identification, and natural history), and a shaded map showing known or expected distribution in Maricopa County and, in some cases historical distribution (mostly for species now extirpated from greater Phoenix). The accounts are prefaced by short sections on viewing amphibians and reptiles, snakebite and toad toxins, and maps of recreation areas and community types, as well as a series of habitat photos. The book closes with a glossary and combination checklist and index. This inexpensive and well illustrated field guide will be a handy reference for anyone visiting Phoenix or the Sonoran Desert.

Vernal Pools, Natural History and Conservation, by Elizabeth A. Colburn. 2004. The McDonald & Woodward Publishing Company, Granville, Ohio (www.mwpubco.com). xiii + 426 pp., 16 pls. Softcover. US $29.95. ISBN 0-939923-91-2. Hardcover. US $39.95. ISBN 0-939923-92-0.

This volume is a complete guide to the natural history of vernal pools of the northeastern United States and eastern Canada. After introducing the hydrology and physical characteristics of vernal pools, the book catalogues the organisms that are associated with these wetland habitats, emphasizing invertebrate groups (especially crustaceans, insects, and other arthropods) and amphibians. The amphibian chapter occupies 43 pages and discusses the identifying features, life histories, eggs, larve, migration, home ranges, and mortality of 18 species of frogs and salamanders that are as-

sociated with vernal pools in the area under consideration. A short chapter discusses other terrestrial vertebrates, providing some data on four turtles and mentioning a few snake species that are sometimes associated with ephemeral wetlands. Ecosystem processes in vernal pools are outlined in a chapter on energy flow, community composition, and seasonal cycles. The remaining text is devoted to the conservation of vernal pools and treats issues such as threats, regulation, and conservation strategies and priorities. The main text is supplemented by an extensive glossary and a 64 page appendix of the fauna of temporary pools and ponds conclude the book. The latter is extensively annotated and contains much relevant information about vernal pools faunas beyond the focal area of the book. *Vernal Pools* is fully referenced, with a bibliography of about 1000 items, including nearly 200 relating to amphibians alone. The book concludes with a subject index and includes a 16 page insert of color plates (five depicting amphibians and reptiles) of varying quality. This book will be useful for herpetologists, entomologists, ecologists and other naturalists throughout the cool temperate regions of eastern North America. It would make an especially valuable adjunct to courses on field ecology or natural history and its extensive bibliography makes it useful for even those already intimately familiar with the fauna of vernal pools and temporary ponds.

Terrarien Atlas. Band 2, Frösche, by Hans-Joachim Hermann. 2004. Mergus Verlag GmbH für Natur- und Heimtierkunde, Melle, Germany (www.mergus.com). 1099 pp. Hardcover. 42,00 Euro (approx. US $53). ISBN 3-88244-073-2.

At almost 1100 pages, this frog atlas is nearly as thick as it is wide. It provides species accounts for hundreds of frogs, including nearly all that are regularly kept in terraria as well as many less common species. Each account provides scientific name and describer, German common name, original scientific name, and statements about distribution, habitat, type of terrarium required, diet in captivity, reproduction, and occasionally additional (often taxonomic) remarks. Representatives of the Bufonidae, Dendrobatidae, Hylidae, Centrolenidae, Leptodactylidae, Myobatrachidae, Hyperoliidae, Rhacophoridae, Mantellidae, Ranidae, Microhylidae, and Nasikabatrachidae are featured. There are typically two accounts per page and, in most cases, the species discussed are illustrated by color photos on the facing page. In many instances, however, additional species are illustrated and for some species habitats, eggs and larvae are also shown. Nearly all the photos are sharp, well composed, appropriately cropped, and large enough to give the reader a good idea of what each frog looks like. Although not all species or even families are covered, more than 1500 species are depicted, making this a very representative guide. The atlas is aimed at herpetoculturalists and will no doubt be a useful reference for those looking for a basic guide to parameters important for husbandry. However, the huge collection of photographs presented in the book make it a useful resource even for professional herpetologists, allowing anyone to "put a face with a name." For this reason this book should be attractive even to those who cannot read the German text.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.html>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information below) or from the SSAR web page (http://www.ssarherps.org/pdf/Adrates.pdf).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Dr. Theodora Pinou, SSAR Treasurer, Western Connecticut State University, Department of Biological & Environmental Sciences, 181 White Street, Danbury, Connecticut 06810, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below), regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6

ARTICLES

TECHNIQUES

The habituation curves of the rattle response for subjects D1, D3, and D12 are shown in Fig. 2. Note the high probability of response in the first 50 trials for all three individuals (mean ± SE = 0.99 ± 0.007 for all three individuals combined). Following the dishabituating stimulus, all snakes responded. It is evident that the rattlebox is useful in consistently eliciting a rattle response and in detecting individual differences in rattling behavior.

In addition to habituation, the rattlebox can also be used to study classical conditioning in rattlesnakes. Our laboratory has just begun to test classical conditioning in rattlesnakes in which the opening and closing of the box serves as an aversive unconditioned stimulus. To serve as a conditioned stimulus, we have mounted a 60 W incandescent light on the inside of the box. Temporarily turning on the light serves as a conditioned stimulus.

We have also designed an operant procedure that utilizes the rattlebox. In operant conditioning, a subject's response is reinforced by its consequences. By placing the rattlebox in a cold room and positioning a heat lamp inside wired to a voice-activated relay, each rattle response is rewarded with an increase in ambient temperature. Because rattling typically does not occur spontaneously, it can be shaped by gently prodding the snake with a snake hook through the keyhole.

The results presented here demonstrate the utility of the rattlebox in studies of learning in rattlesnakes. Specifically, Western Diamondback Rattlesnakes repeatedly exposed to an aversive yet harmless stimulus show a learned decrease in rattling. Furthermore, the box is relatively inexpensive and can be built in one day. Extension of the rattlebox to studies of classical and operant conditioning is also easily accomplished. We hope this apparatus will shed light on the perceptual world of rattlesnakes and stimulate further research in the area of learning in snakes.

Acknowledgments.—Development of the apparatus was funded by a grant from the East Texas Herpetological Society to AJP. B. Baker, B. Wilson, and H. Schlothower provided the snakes. N. Birnbaum, N. Faught, and L. Hyde assisted in data collection. An anonymous reviewer made helpful comments on an earlier version of the manuscript.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 36, Number 1 (March 2005).

CAUDATA

AMBYSTOMA OPACUM (Marbled Salamander). **SPERMATOPHORE DEPOSITION.** On 4 Nov 2000, a lone male *Ambystoma opacum* was observed depositing a spermatophore at Ginger's Bay, a small Carolina Bay on the Savannah River Site in Aiken Co., South Carolina. The nearest conspecific, another male, was more than 3 m away during deposition, too great a distance to have influenced the sexually active male by female mimicry (Arnold 1976. Z. Tierpsychol. 42:247–300). Because spermatophore deposition in *A. opacum* occurs very rapidly, with certain individuals achieving as many as 4 depositions in as short as 30 seconds (pers. obs.), there was not sufficient time for another salamander to have interrupted normal courtship with this male, leaving him alone to be observed in an attempt to finish mating. A search of the immediate vicinity yielded no other spermatophores. Previous reports of courtship in *Ambystoma* have emphasized the tendency for males to deposit spermatophores repeatedly, but only in the presence of other courting individuals (e.g., Noble and Brady 1933. Zoologica 11:89-132; McWilliams 1992. Behaviour 121:1–19). These lines of evidence strongly suggest that this individual was engaging in spermatophore deposition in the absence of courtship or influence by either past or present male sexual activity. Males of congeneric species have been reported to deposit in solitude but only after being initially stimulated by mating aggregations or courtship behavior by conspecifics (Anderson 1961. Copeia 1961:132–139; Arnold 1976. *op. cit.*; McWilliams 1992. *op. cit.*). Because males presumably are limited in the number of spermatophores they can produce in a breeding season (Verrell 1986. J. Comp. Psych. 100:291–295; Verrell 1988. J. Herpetol. 22:394–400), selection should strongly favor male mating strategies that result in successful insemination of females. Thus, if isolated spermatophore

deposition is common, we might expect some female *A. opacum* to select previously deposited spermatophores without submitting to ritualized mating. Courtship avoidance may be advantageous for females if substantial costs are incurred by participating in mating aggregations (e.g., increased predation risk, Koga et al. 1998. Proc. Roy. Soc. Lond. B 265:1385–1390). Others have indicated that males sometimes deposit spermatophores when only other males are present and that females may accept spermatophores in the absence of courtship (Scott 2005. *In* Lannoo [ed.]., Amphibian Declines: The Conservation Status of United States Species, pp. 627–632. University of California Press, Berkeley, California). These observations suggest that *A. opacum* may exhibit two different mating strategies: 1) courtship either in the terrestrial habitat or in dry pond basins (Krenz and Scott 1994. Herpetologica 40:46–50) and 2) courtship avoidance in which males deposit spermatophores in isolation or on the periphery of aggregations and females search for spermatophores that have been left behind by unsuccessful courtship encounters and random depositions. Detailed experimental and observational studies are needed to determine the importance and frequency of these mating behaviors in marbled salamanders.

Submitted by **DEAN A. CROSHAW**, Savannah River Ecology Laboratory, Drawer E, Aiken, South Carolina 29802, USA and Department of Zoology, University of Oklahoma, 730 Van Vleet Oval, Norman, Oklahoma 73019, USA; e-mail: croshaw@srel.edu.

CRYPTOBRANCHUS ALLEGANIENSIS (Hellbender). **DISPLACEMENT BY A FLOOD.** Hellbenders maintain small home ranges, usually occupying an area of ca. 90–346 m² (Peterson and Wilkinson. 1996. Herpetol. Rev. 27:126–127; Coatney 1982. MS Thesis, Southwest Missouri State Univ.; Hillis and Bellis 1971. J. Herpetol. 5:121–126; Humphries and Pauley, unpubl. data). In one study (Nickerson and Mays 1973. The Hellbenders: North American Giant Salamanders. Publ. Biol. Geol., Milwaukee Public Mus. 106 pp.), an intercapture distance of over 900 m by one Hellbender was recorded, and another individual covered a roundtrip distance of 1050 m over a several-month period. Large floods could dislodge Hellbenders from a hiding rock, possibly displacing them long distances downstream from their home range. On 10 Sept 2004, western North Carolina experienced massive flooding resulting from the remnants of Hurricane Francis. Some areas received over 50 cm of rain over a two-day period. I was contacted by a resident of Black Mountain, North Carolina who found an adult Hellbender in a drying puddle in her front yard. Flat Creek (Buncombe County), which usually averages 2–3 m in width, flooded the houses along the floodplain, leaving the hellbender stranded in the yard. The hellbender was described as "almost dead" by the homeowner. The homeowner provided a photograph of the hellbender, measured it, and determined its gender based on swelling of the cloaca. It was an adult female with a total length of >50 cm. This observation suggests that large floods can displace or lethally strand some hellbenders.

Submitted by **W. JEFFREY HUMPHRIES**, Department of Forestry and Natural Resources, Clemson University, Clemson, South Carolina 29634, USA.

CRYPTOBRANCHUS ALLEGANIENSIS (Hellbender). **CANNIBALISM.** Hellbenders prey mainly on crayfish, though a variety of other invertebrates and vertebrates are sometimes taken (Nickerson and Mays 1973. The Hellbenders: North American Giant Salamanders. Milwaukee Public Mus. Press, 106 pp.). Hellbenders have also been known to feed on eggs and larvae of their own species (Smith 1907. Biol. Bull. 13[1]:5–39). Here we report an adult Hellbender having eaten a smaller conspecific in Pisgah National Forest, Transylvania County, North Carolina. On 22 June 2004, we captured an adult male Hellbender (SVL = 23.6, TL = 37.2 cm) that regurgitated another Hellbender (SVL = 12.6, TL = 18.5 cm) during data collection. The population of Hellbenders in this particular stream is very dense, and consists of all size classes (Humphries, unpubl. data). Taber et al. (1975 Copeia 1975:633–639) suggested that cannibalism might be an important population control mechanism. Though cannibalism of larval Hellbenders has been documented, our finding of a small adult eating an immature adult half its size is noteworthy.

Submitted by **W. JEFFREY HUMPHRIES**, Department of Forestry and Natural Resources, Clemson University, Clemson, South Carolina 29634, USA; **MAURICIO SOLIS** and **CLAIRE CARDWELL,** Department of Biological Sciences, University of Missouri-Rolla, Rolla, Missouri 65409, USA; and **AMY SALVETER,** U.S. Fish and Wildlife Service, Ecological Services, 101 Park DeVille Drive, Suite A, Columbia, Missouri 65203, USA.

EURYCEA NEOTENES (Texas Salamander). **HABITAT UTILIZATION.** Populations of the Texas Salamander are thought to be restricted to cave waters or the immediate vicinity of springs that flow from limestone formations (Sweet 1982. Herpetologica 38:430–444). The following observation was made in a pool within close proximity to a river separated from any immediate detectable seepage or other source of water flowing into the river. On 29 April 2001 at 1200 h, three adult *Eurycea neotenes* were found on the south bank of the Sabinal River in Lost Maples State Park, Bandera County, Texas. All three specimens were observed in an isolated pool near the river's edge at depths 5–20 mm. Fallen and submerged sycamore leaves (*Platanus* sp.), were near all individuals. Air temperature was ca. 14.4°C and the water temperature was noticeably warmer, but exact water temperature was not available. Several springs and seepages are present along the Sabinal River and were possibly the origin of these salamanders. Two specimens were creamy white and closely matched the color of the limestone pebbles. *Eurycea neotenes* typically displays brownish hues. The paler coloration could be the result of polymorphism, age, or environmental adaptation. None of the specimens were collected as they escaped by burrowing into the matrix of riverbed gravel upon the slightest disturbance of the water. Several tadpoles of Blanchard's Cricket Frog (*Acris crepitans*), Gulf Coast Toad (*Bufo nebulifer*), and Rio Grande Leopard Frogs (*Rana berlandieri*) were present in the pool as were Large Spring Gambusia (*Gambusia geiseri*). This observation documents the presence of adult *Eurycea neotenes* in close association with a river, and also demonstrates a means by which they move through their rocky microhabitat in both troglobitic and riverine settings.

PLETHODON GLUTINOSUS (Slimy Salamander). **PREDATION.** The published list of predators of *P. glutinosus* is short. This may be due in part to the sticky skin secretions that are the namesake of this species (Brodie et al. 1979. Copeia 1979:270–274). Cannibalism occurs as well (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 587 pp.). Here we report an instance of predation on *P. glutinosus* by an aquatic vertebrate.

During the night of 11 May 2003, a Blue Catfish (*Ictalurus furcatus*) ca. 75 cm TL was caught on hook and line. The stomach contents included two *P. glutinosus*, one was mostly digested and the other was an intact adult. This fish was caught ca. 0.5 km upstream of the confluence of Channahatchee Creek and the Tallapoosa River (Yates Reservoir) in Elmore County, Alabama USA. The diet of the Blue Catfish is largely comprised of invertebrates such as mollusks and crayfish; known vertebrate prey includes fish and frogs (Jenkins and Burkhead 1994. Freshwater Fishes of Virginia. American Fisheries Society, Bethesda, Maryland. 1079 pp.).

May 2003 was characterized by unusually heavy precipitation, with rainfall on 9 May resulting in severe flooding upstream of Yates Reservoir. A comparison of USGS average flow rates (measured ca. 55 km upstream at Horseshoe Bend) for this time of year (9013 cfs) and those experienced during this event (116100 cfs), illustrate the magnitude of this flood. It is assumed that the inundation of the riparian zone of the Tallapoosa River and the impoundments along its length made it possible for an aquatic vertebrate to prey upon an entirely terrestrial amphibian.

PSEUDOTRITON RUBER (Red Salamander). **REPRODUCTION**. Few nests of the Red Salamander have been found. Bishop (1925. Nat. Hist. 25:385–389) described the first known clutch of eggs for this species. Based on the date of discovery (3 October) and advanced developmental stage of the embryos, Bishop (1941. New York St. Mus. Bull. 324:1–365) suggested oviposition occurs as early as mid-September in the northern portion of the range. As further support of this suggestion, Bishop (1941, *op. cit.*) reported that Twitty and Hutchinson found 290 eggs of this species during the first week of November. The embryos ranged from "near hatching to less advanced," suggesting to Bishop that the eggs were laid during late fall and early winter months, and that they represented several clutches from different females. Since these early accounts, only Fowler (1962. Bull. Virginia Herpetol. Soc. 31:4) reported finding nests of *P. ruber*. Clutch size, as determined from the aforementioned natural clutches and counts of mature oviducal eggs (Bruce 1978. Copeia 1978:417–423), ranges from 29–130 and is positively correlated with female SVL. Here, we report a nest of the Red Salamander found in the twilight zone of a cave located along the banks of the Caney Fork River in DeKalb County, Tennessee.

On 19 Sept 2004, we found a clutch of sixty-three eggs packed together tightly and attached by a slender stalk to the undersurface of a rock (Fig. 1) located in the center of a small, out-flowing cave stream. The rock was partially embedded in gravel; water flowed around the edges, but not over the upper surface. The lower surface of the rock sat above a shallow, water-filled depression; the eggs dangled into the depression and were bathed in low-velocity subsurface flow. Two adult *P. ruber* inhabited the depression, possibly in attendance of the eggs. The eggs were white and cleavage planes were not discernible, indicating that the eggs had been laid recently.

This is the first record of a nest of *P. ruber* in Tennessee and helps support the claims of others (Pfingston and Downs [eds.] 1989. Salamanders of Ohio. Ohio Biol. Surv. Bull. New Ser. Vol. 7) that oviposition occurs deep in springs (here a cave stream).

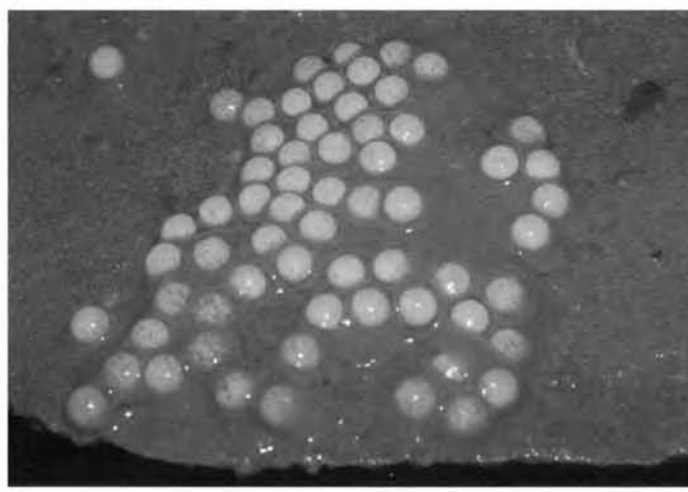

FIG. 1. Eggs of the Red Salamander from Dekalb County, Tennessee.

ANURA

BUERGERIA JAPONICA (Ryukyu Kajika Frog). **OVIPOSITION BEHAVIOR.** *Buergeria japonica* is a small (25–37 mm), terrestrial rhacophorid that occurs on the Ryukyu Archipelago of Japan and Taiwan. The species ranges from maritime lowlands to montane forests, where it deposits small (1.2–1.4 mm diam) eggs in lentic and lotic waters (Maeda and Matsui 1989. Frogs and Toads of Japan. Bun-ichi Sogo Shuppan, Tokyo, pp. 170–173). *Buergeria japonica* is known to deposit eggs in small clusters, but detailed

reports of the oviposition sequence are lacking. Hence, I describe two oviposition sequences for *B. japonica* from the island of Okinawa, Japan.

Observations were made in a small (1–15 cm deep x 0.7–8.7 m wide) coastal stream in the northern part of Okinawa (26°50'N, 128°17'E, elev. < 1 m) at an area near the sandy beach at its mouth. In this area, limited weedy vegetation exists along the stream; the substrate is largely pebbles, sand, and coral fragments. The study site encompassed an area from the stream mouth to ca. 230 m upstream. The seawater prism usually moves only about 100 m upstream from the mouth at high tide.

All observations were made during moonlit nights on 1 and 13 Sept 2002. At 0319 h on 1 Sept, I encountered an amplectic pair (Pair 1) motionless on the ground ca. 30 cm from the stream edge and ca. 180 m upstream from the stream mouth. The pair remained motionless for several minutes, and began moving at 0330 h. After the pair had made 4 short (< 1 m) moves between the stream and bank, the female backed into the stream and began to lay eggs at 0345 h. While laying eggs, the female pressed eggs against the streambed using her hindlimbs. Egg laying continued for ca. 1 min. At 0346 h, the pair moved to a new spot ca. 20 cm away, and the female again laid eggs. The pair repeated this general movement-oviposition sequence until I lost sight of them (0409 h). However, the female did not deposit eggs every time the pair returned to the stream; sometimes the female stayed motionless for several seconds and then moved to a new spot. I observed 14 distinct bouts of oviposition and 19 movements during my 50 min observation of this pair. During an oviposition bout, 1–6 eggs were deposited in each cluster.

At 0308 h on 13 Sept, I found another amplectic pair (Pair 2) in the stream ca. 190 m upstream from the mouth. Oviposition behavior was similar to that of Pair 1. Until the male left the female at 0408 h, Pair 2 had engaged in 9 bouts of oviposition and 14 movements. The number of eggs in each cluster ranged from 1–6. In the early morning of the day after I observed each pair, I counted the number of eggs within a 1 m^2 area in the vicinity of the oviposition observations. The search area scale reflected the movement scale of each pair, which was well within a unique 1 m^2 area. As I saw no other pairs lay eggs in these areas each night, egg counts are thought to reflect that of each pair. Eggs counted within each 1 m^2 were 38 and 53 for Pairs 1 and 2, respectively.

A closely related species, *B. buergeri*, also lay eggs in several clusters, but the number of eggs in each cluster ranged from 50–80 (Maeda and Matsui, *op. cit.*), and the species is much larger than that of *B. japonica.*

As several abiotic factors such as high salinity (Beebee 1985. Herpetol. J. 1:14–16; Viertel 1999. Amphibia-Reptilia. 20:161–171), desiccation, and occasionally increasing flow might place *B. japonica* eggs at risk in maritime reproductive habitats, partitioning clutches into small clusters of eggs may increase opportunities for offspring survival.

BUFO CRUCIFER (Striped Toad). **JUVENILE SPATIAL DISTRIBUTION.** *Bufo crucifer* is a neotropical toad with a wide distribution through Missiones, Argentina; northeastern, eastern, and southeastern Brazil; and eastern Paraguay (Frost 2002. Amphibian Species of the World – an online reference, July, 2002. V2.21). Although *B. crucifer* is a common toad in Brazilian flooded habitats, there is little information about its reproductive biology or natural history (Haddad and Bastos 1997. Amphibia-Reptilia 18:295–298; Haddad and Sazima 1992. *In* Morellato org., História Natural da Serra do Japi: Ecologia e Preservação de uma Área Florestal no Sudeste do Brasil, pp. 188–211. Campinas, Editora UNICAMP). Here we present new information on the ecology of this poorly known neotropical toad: the possible influence of physical environment, and body size in the spatial distribution of *B. crucifer* juveniles.

During three consecutive days in September 2002 (dry season) we documented the spatial distribution of *B. crucifer* juveniles (including newly metamorphosed specimens) in a permanent pond (about 1320 m^2) located in a cleared area inside Atlantic rain forest domains (*sensu* Ab'Saber 1977 Geomorfologia 52:1–23) on Reserva Biológica União (22°31'S, 41°56'W), municipality of Casimiro de Abreu, State of Rio de Janeiro, southeastern Brazil. Data were recorded using a belt transect of 0.5 m x 2.0 m (Brower and Zar 1984. Field & Laboratory Methods for General Ecology. Wm. C. Brown Publishers, Iowa. 226 pp.) along 62 sites at the edges of the pond (from water to a distance of 6.0 m from water). We captured all juveniles observed, recorded the distance from water, and habitat features including substrate type (soil moisture: flooded, muddy, moist-firm ground, and dry ground) and vegetative cover (none, scarce, and abundant) of the microhabitat. In each capture juvenile SVL was measured to the nearest 0.1 mm with calipers, recording the individuals with tail remnants. After measurements the juveniles were released at the capture site.

We investigated associations between juvenile capture location

TABLE 1. Median and range value of SVL of *Bufo crucifer* juveniles along a pond shoreline according to distance class, substrate type, and vegetation cover, and Kruskal-Wallis test.

Categories of	Median SVL (N) (mm)	SVL Range (mm)	Kruskal-Wallis test (χ^2; p value)
distance (m) / sampled sites			
0 – 1 / 12	8.0 (N = 228)	6.5 – 9.9	110.11; 0.00001
1 – 2 / 12	8.6 (N = 96)	6.8 – 12.8	
2 – 3 / 12	9.1 (N = 83)	7.6 – 13.0	
3 – 4 / 10	8.6 (N = 68)	7.2 – 12.0	
4 – 5 / 8	(N = 0)		
5 – 6 / 8	14.2 (N = 6)	11.4 – 19.0	
substrate type			
dry ground	9.8 (N = 50)	8.0 – 13.0	107.51; 0.00001
moist-firm ground	8.6 (N = 216)	6.8 – 19.0	
muddy	8.2 (N = 81)	6.8 – 9.9	
flooded	7.9 (N = 134)	6.5 – 9.2	
vegetation cover			
none	8.0 (N = 18)	6.8 – 9.6	17.26; 0.0002
scarce	8.0 (N = 69)	6.8 – 13.0	
abundant	8.4 (N = 394)	6.5 – 19.0	

TABLE 2. Multiple regression parameters explaining the variance in *Bufo crucifer* juvenile SVL. For each predictor variable, the parameters shown are the slope ± standard errors, t-test, and significance level.

Variables	Slope ± s.e.	t (476)	p-level
Distance from water	0.001 ± 0.0005	3.05	0.002
Substrate type	-0.492 ± 0.063	-7.79	< 0.0001
Vegetation cover	0.593 ± 0.099	5.95	< 0.0001

and habitat features with juvenile SVL through non-parametric Spearman correlation coefficient (r_s) (Zar 1984. Biostatistical Analysis. Englewood Cliffs, Prentice-Hall, London. 718 pp.). For each 1 m interval we calculated the median and range of SVL, recognizing six distance classes, and examined differences between classes with a Kruskal-Wallis test. The relationship between physical factors (distance from water, substrate type, and vegetation cover) and juvenile SVL was examined with stepwise multiple regression (Zar 1984, *op.cit.*).

A total of 481 juvenile *B. crucifer* were captured along the transects. Juvenile SVL was positively correlated with distance from water ($r_s = 0.52$; $p < 0.0001$) and vegetation cover ($r_s = 0.24$; $p < 0.0001$), and negatively correlated with substrate type (flooded, muddy, moist-firm, and dry ground, in that order; $r_s = -0.56$; $p < 0.0001$), indicating that the smallest individuals were found in microhabitats with scarce vegetation cover and higher soil moisture. Substrate type was negatively correlated with distance from water ($r_s = -0.78$; $p < 0.001$; N = 511). Median and range values of juvenile SVL for each distance class, substrate type, and vegetation cover are presented in Table 1.

Regarding the relationship between such physical factors and juvenile SVL, the three predictor variables were selected by the forward step-wise model, explaining only 30% of variance in juvenile SVL ($F [3,476] = 62.71$; $p < 0.000001$; N = 480) (Table 2). As the tolerance of each variable in the regression was not small (substrate type = 0.59; vegetation cover = 0.97; distance from water = 0.57), the regression could be evaluated, and the contribution of each variable to the regression analysis was not redundant.

According to Duellman and Trueb (1986. Biology of Amphibians, McGraw-Hill, New York. 670 pp.), movement patterns probably reflect age-specific variation in life history strategies with subsequent differences in ecological requirements. Thus, it is expected that newly metamorphosed juveniles will be found in sites with higher soil moisture and nearer water, as we found in the distribution data. On the other hand, the largest juveniles tended to depart from the water body and search for vegetation cover, which can be associated with capture of prey, protection from solar exposure, or predation avoidance.

BUFO MARINUS (Cane Toad). **AMPLEXUS DISPLACEMENT.** Studies of sexual selection in anurans are mainly based on the relationship between reproductive success and body size, which could overlook the role of sexual selection on specific body parts (Howard and Kluge 1985. Evolution 39:260–277; Heatwole and Sullivan 1995. Amphibian Biology, Vol. 2, Surrey Beatty & Sons). For example, in *Bufo marinus* (to 230 mm SVL) sexual selection benefits the reproductive success of larger mature males, which have larger forelimbs that allow a strong amplexus (Lee 2001. Copeia 2001:928–935). It has also been proposed that sexual selection might act on reproductively larger males which have larger hind limbs allowing them to defend the amplexus position against unpaired males (Lee and Corrales 2002. J. Herpetol. 36:502–505). Unfortunately, most of the knowledge on the reproductive behavior in *B. marinus* is based on anecdotes or on measurements of preserved specimens (Lee 2001, *op. cit.*; Lee and Corrales 2002, *op. cit.*), thus providing only partial evidence in favor of larger hind limbs in *Bufo* as the result of sexual selection. Here I document details of amplexus displacement in *B. marinus* in the field.

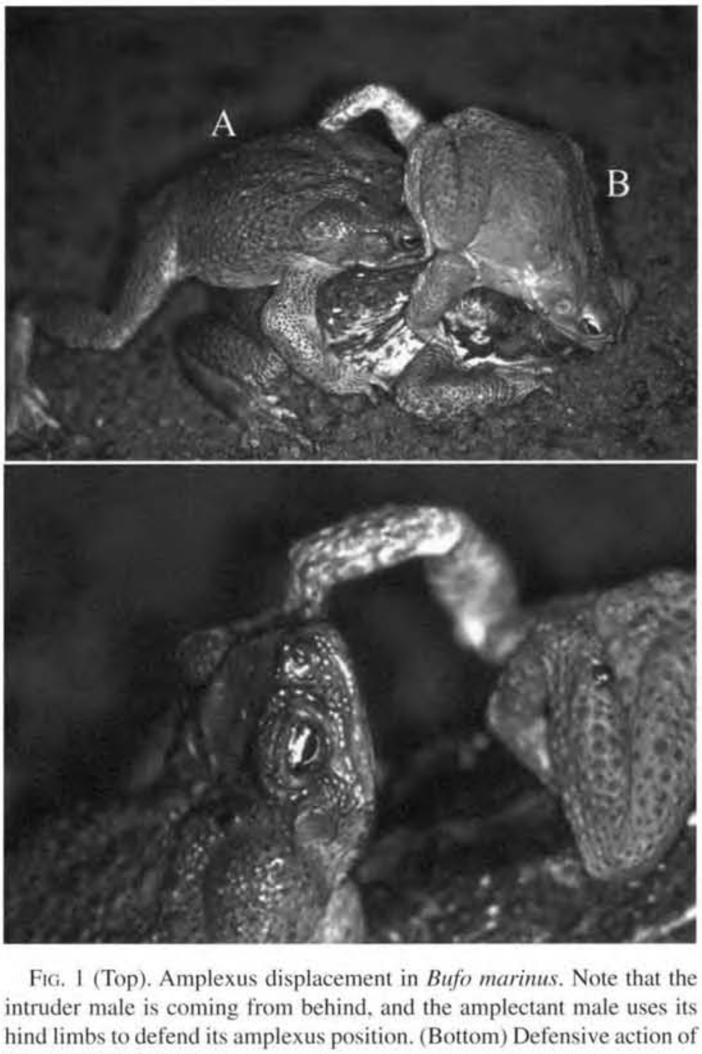

FIG. 1 (Top). Amplexus displacement in *Bufo marinus*. Note that the intruder male is coming from behind, and the amplectant male uses its hind limbs to defend its amplexus position. (Bottom) Defensive action of the amplectant male.

On 27 Aug 2003 at 0345 h, I observed a male (115.5 mm SVL, 48.79 mm hindlimb length [HL], 15.1 mm hindlimb thickness[HT]) attempting amplexus displacement of an amplectant male (105 mm SVL, 41.2 mm HL, 13.31 mm HT) from the dorsum of a female (140 mm SVL) in a semi-permanent pond in Region San Antonio, Quebradillas, northwestern Puerto Rico (18º25.113'N; 66º54.266'W). The intruder male approached the amplectant male from the posterior end and the amplectant male kicked the intruder with its hindlimb and emitted a liberation call. The intruder male ("A" in Fig. 1 top) continued amplexus displacement by pushing its head between the abdomen of the amplectant male ("B" in Fig. 1 top) and the female's dorsum (Fig. 1 top). The intruder male pushed its head forward and embraced the female posterior-laterally with its forelimbs while getting firm support on the ground with its hindlimbs. The amplectant male pushed the intruder male in the head with its hindlimb (Fig. 1 bottom). After a break, the intruder pressed its head firmly against the dorsum of the female. After 56 minutes of fighting and defense, the intruder displaced the smaller amplectant male from the female dorsum. The female was crawling slowly throughout the process of amplexus displacement without hesitation or attempting escape. The last ten minutes of a second successful amplexus displacement was observed that night (intruder male 120 mm SVL, 48.77 mm HL, 16.09 mm HT; amplectant male 106.5 mm SVL, 41 mm HL, 14.25 mm HT; female 113 mm SVL). The pattern of amplexus displacement was similar to the one described here.

These events of amplexus displacement are consistent with the idea of sexual selection resulting in sexual dimorphism of hindlimbs in *B. marinus* (Lee and Corrales 2002, *op. cit.*). It is expected that in other anurans with amplexus displacement, sexual selection might promote sexual dimorphism of morphological traits.

I thank Neftalí Rios, Paul David Gutierrez, and Fernando Montealegre for valuable comments on earlier versions of the manuscript. The observations were during fieldwork supported by the University of Puerto Rico, and IDEAWILD.

Submitted by **FERNANDO VARGAS-SALINAS**, Department of Biology, University of Puerto Rico-Río Piedras Campus, PO Box 23360, San Juan, Puerto Rico, 00931-3360; e-mail: vargassalinasf@yahoo.com.

BUFO OCCIDENTALIS (Pine Toad). **ALTITUDINAL DISTRIBUTION.** This endemic Mexican toad is widely distributed in the Sierra Madre Occidental of Sonora and Chihuahua southward through the Transvolcanic Zone, including the states of Veracruz, Puebla, Tlaxcala, Morelos, and Mexico (Santos-Barrera 1995. Tesis Maestría en Ciencias. UNAM). It has been recorded from 2000 m elevation in Aguascalientes and Jalisco (Chrapliwy 1956. Herpetologica 12:121–124). In spite of being a relatively common species, few natural history data are available.

We collected specimens at 2310 m elev. on the plateau of Cerro Chacatecas, Municipio Zapotitlán Salinas, Puebla. A female (LOL field series 146, SVL 55.5 mm) was found 9 April 2004, at 0530 h within a few meters of a cabin. Another female (LOL field series 157, SVL 41.8 mm) was caught at the same place on 7 May 2004, at 1341 h inside a pit (1.0 x 0.8 m, 40 cm deep). In the same pit a male *Eleutherodactylus nitidus* (LOL field series 155, SVL 30 mm) and a male *Spea multiplicata* (LOL field series 156, SVL 49.2 mm) were found, both very emaciated.

Apparently *Bufo occidentalis* can move long distances, as known for some other species of the genus; Heusser (1968. Rev. Suisse Zool. 75: 927–982) mentioned that *B. bufo* moves and forages up to 3 km from its home refuge. Where the present specimens were found there were no permanent ponds within a radius of several kilometers; the nearest is almost 1 km below the plateau of Cerro Chacatecas, and the intervening topography is very rugged.

The *B. occidentalis* are in the Laboratorio de Ecología, UBIPRO, UNAM as UBIPRO 13846–13847.

BUFO TERRESTRIS (Southern Toad). **DIET AND SCAVENGING BEHAVIOR.** On the night of 25 Sept 2004, during intermittent rain and moderate wind preceding Hurricane Jeanne, we were photographing juvenile River Frogs (*Rana heckscheri*) as they migrated across a paved campground road from a large pond (Ocean Pond, Osceola National Forest, ca. 4.2 km NNW Olustee, Baker County, Florida, USA). Several of the juvenile *R. heckscheri* had been killed by vehicles, and we noticed a moderately large adult *B. terrestris* sitting on the pavement, focused intently on the flattened carcass of one. Several small ants of undetermined species were feeding on the dead frog, and we presumed the toad to be attempting to feed on the ants. The toad was removed from the pavement to prevent its death in the event that a vehicle came. A few min. later, it had returned to its original position and was again focused on the frog carcass. We turned our attention elsewhere for less than 1 min., and looked back to discover that the toad had swallowed the carcass—probably accidentally as it responded to the movement of the few ants feeding on it. One hind foot of the frog was still visible, protruding from the toad's mouth. After less than 1 min., the toad moved off and out of sight into the roadside grass. Juvenile *R. heckscheri* have been reported to be toxic or distasteful to some predators (Behler and King 1985. The Audubon Society Field Guide to North American Reptiles and Amphibians. Alfred A. Knopf, New York. 743 pp.). We do not know if the toad suffered ill effects or regurgitated the frog later. *Bufo terrestris* is an indiscriminate feeder, but to our knowledge there are few if any reports of scavenging in the species, and no others of its taking *R. heckscheri* as food. Such apparent "accidental scavenging" may be more common than reports indicate among anurans that are relatively indiscriminate feeders.

Box 122, West End, North Carolina 27376, USA (e-mail: tpusser@carolina.net).

ELEUTHERODACTYLUS ALBIPES (NCN). **REPRODUCTION.** *Eleutherodactylus albipes* is only known from the Sierra Maestra of eastern Cuba (Estrada and Ruibal 1999. *In* Crother [Ed.], Caribbean Amphibians and Reptiles, pp. 31–62. Academic Press, San Diego, California; Hedges 1999. *In* Duellman [Ed.], Patterns of Distribution of Amphibians, A Global Perspective, pp. 211–254. Johns Hopkins University Press, Baltimore and London). It inhabits the leaf litter of cloud forests above 800 m (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History. Florida Univ. Press, Gainesville, 720 pp.). In this paper we provide the first data on clutch size and parental care in this endemic Cuban frog.

During a herpetological expedition to the Pico Turquino in the Sierra Maestra during June 2003, we found an adult female *Eleutherodactylus albipes* (Fig. 1 [top]; SVL = 31.25 mm) in the bushy forest of the Pico Turquino summit (19°59'20.8"N; 76°50'09,8"W, NAD27 for Cuba, 1974 m). The frog was underneath a stone in a small cavity (70 x 40 mm), with a clutch of 42 eggs (mean 4.3 mm diam). Developmental stage was 11 or 12 of the table developed by Townsend and Stewart (1985. Copeia 1985:423–436) for *E. coqui*. The grayish embryos showed great mobility, conspicuous eyes, and the legs were visible (Fig. 1 bottom). However these results should be considered carefully because *E. albipes* belongs to a different subgenus (*Euhyas*) than *E. coqui* (*Eleutherodactylus*).

Fig. 1. Adult female of *Eleutherodactylus albipes* (top) and her nest with visible embryos (bottom).

When we removed the stone and leaves, the female remained over the nest in a protective posture, which could be evidence of parental care. *Eleutherodactylus albipes* appears to be a "ground nester" and a "good species" according to Townsend (1996. *In* Powell and Henderson [Eds.], Contributions to the West Indian Herpetology: A Tribute to Albert Schwartz, pp. 229–239. SSAR Contributions to Herpetology. Vol. 12, Ithaca, New York). Our find corroborates this characterization, considering that the nest was discovered in a hole in soil under a rock, and the adult female refused to abandon the nest when disturbed.

Juan Llamacho and Alexis (Turquino guide) helped with fieldwork. Photographs were taken by Julio Larramendi. The Spartakus Foundation of Finland and the Instituto de Ecología y Sistemática and the Centro Oriental de Ecosistemas y Biodiversidad (BIOECO) from Cuba, partly funded the field expedition. Special thanks also to the workers of the Turquino National Park for their hospitality and help during the field expedition.

ELEUTHERODACTYLUS WIGHTMANAE (Coquí Melodioso). **REPRODUCTION.** *Eleutherodactylus wightmanae* is a small frog (22.5 mm SVL maximum for females), found in the interior uplands of Puerto Rico. Females are found on the forest floor and males call from vegetation up to 0.6 m above ground (Joglar 1998. Los Coquíes de Puerto Rico: Su Historia Natural y Conservación,

Fig. 1. *Eleutherodactylus wightmanae* egg clutch inside a folded *Cecropia* leaf.

Editorial de la Universidad de Puerto Rico, San Juan, 232 pp.). Herein we provide the first data on clutch size, egg size, and nesting site of *E. wightmanae*. One clutch found 8 April 2003 in the Carite Forest Reserve in Eastern Puerto Rico contained four eggs and was inside a folded *Cecropia* leaf on the forest floor. An adult *E. wightmanae* was also found inside the leaf, suggesting parental care. A second clutch (Fig. 1) was found on 5 Sept 2004 at Las Casas de la Selva, Patillas close to the Carite Forest Reserve. This clutch contained five eggs (mean 4.39 mm diam; 4.31–4.52; N = 3) and was also inside a folded *Cecropia* leaf on the forest floor. The clutch was deposited in the herpetology collection of the Museo de Biología, Universidad de Puerto Rico–Río Piedras (UPR–RP 6273). No adult was found guarding this clutch but parental care in the form of male attendance has been reported for the species (Townsend 1996. *In* Powell and Henderson [Eds.], Contributions to the West Indian Herpetology: A Tribute to Albert Schwartz, pp. 229–239. SSAR Contributions to Herpetology. Vol. 12, Ithaca, New York).

HYALINOBATRACHIUM COLYMBIPHYLLUM **(Glass Frog). EGG MASS DEFENSE.** Males of the centrolenid frog *Hyalinobatrachium colymbiphyllum* remain near their aerial egg masses that are laid on vegetation above streams. Protection of nonaquatic eggs and developing embryos from predators is one benefit of this form of parental care (McDiarmid 1978. *In* The Development of Behavior: Comparative and Evolutionary Aspects, pp. 127–147. Garland STPM Press, New York). A number of insect predators of nonaquatic amphibian egg masses have been reported, including dipterans on *Hyperolius* (Vonesh 2000. Copeia 2000:560–566), other centrolenids (Villa 1977. J. Herpetol. 11:317–322; Villa and Townsend 1983. J. Herpetol. 17:49–68), and rhacophorids (Yorke 1983. J. Herpetol. 18:235–241), as well as hymenopterans on *Agalychnis* (Warkentin 2000. Anim. Behav. 60:503–510). Herein we provide a previously unreported account of *H. colymbiphyllum* defending its egg masses from predation by vespid wasps.

At about 0900 h on 25 May 2000, we observed a male *H. colymbiphyllum* defend two egg masses from vespid predation for about 10 min. in the headwaters of the Río Guabal in Parque Nacional Omar Torríjos Herrera, Coclé Province, Panamá. The male was in a sleeping position, with eyes open, on top of a small leaf overhanging the stream, ca. 1.8 m above the water surface. There was an egg mass on the underside of the same leaf, located about midlength of the leaf and slightly to one side of the midvein. A second egg mass was similarly positioned on the underside of another leaf ca. 8 cm above the frog. A third leaf, devoid of egg masses, was situated midway between these two leaves, with all three leaves arranged in a staircase fashion.

While we were observing the male *H. colymbiphyllum*, a black and yellow vespid wasp (*Polybia* sp.) flew within 10 cm of the frog and the two clutches of eggs. When the wasp flew closer to the frog, the frog kicked at the passing wasp twice, using its left hind leg. The wasp landed on the middle leaf within a few centimeters of the upper egg mass and the alert frog. The frog grabbed the wasp in its mouth and immediately released it. A second, similar wasp approached the upper egg mass, and the frog pursued it by walking onto the middle leaf, where it remained until the wasp flew off several seconds later; the frog returned to its original position on the lower leaf. A third wasp landed near the upper egg mass, walked to the underside of the leaf, and began to consume the gelatinous portion of the egg mass while the other wasps flew within 30–40 cm of the frog and egg masses. The frog continued to defend its egg masses while we captured and preserved one of the wasps for identification. We were unable to witness the subsequent interactions between the frog and wasps, but the frog and both egg masses were absent the following morning, suggesting that the wasps were successful in their predation attempts.

We thank Jeanne Robertson and Cecil Smith for verification of the identification of the organisms, and Karen Lips, Susan Walls, and Ronald Altig for constructive comments that improved this communication. These observations were made while conducting research funded by a NSF SGER grant (NSF DEB #0001615) awarded to Cathy Pringle, Karen Lips, and Susan Kilham.

RANVESTEL**, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA.

HYLA GRATIOSA **(Barking Treefrog). WINTER RETREAT.** An adult male *Hyla gratiosa* (6.5 cm SUL) was found at 1530 h (EST) on 27 Dec 2003 in a shallow body pit in the soil under a piece of oak bark. The retreat was located in a disturbed oak-pine hammock on the east shore of Putnam Prairie, 1.5 km SE of Putnam Hall, Putnam County, Florida. A second, unused depression of similar dimensions was also found under the same bark ca. 10 cm from the frog's current retreat. The depressions were 60 m upslope from an ephemeral pond that had been used the previous summer by this species for breeding.

Upon discovery, the frog was completely visible in the body pit. Its skin was moist, covered with sand, and dark in color (characteristic spots barely discernible). The frog felt cold to the touch. The eyes were closed, and the front legs were tucked forward under the chin. The body pit measured 6 x 7 cm, with a maximum depth of 4 cm. The frog's body nearly filled the cavity. Soil temperature at 4 cm depth adjacent to the body pit was 13.9°C.

The frog was still visible in its pit at 1330 h on 28 Dec 2003, but disappeared from view by 1410 hrs on 29 Dec, moving into a short burrow that extended laterally from the body pit. Although not visible, the frog could be felt in its burrow with a finger. Soil temperatures at this time had increased to 15.6°C. The frog was checked irregularly 43 times day and night during the 70-day period that it spent in this retreat. During this period, soil temperatures ranged from 8.0–21.4°C, and there were five major rain events associated with cold fronts moving through north Florida. There was no evidence that the frog had left its retreat during its entire

internment. The frog disappeared sometime between 1730 h on 5 March 2004 and 0800 h the next morning. The soil temperature had risen to 22.4°C at the time of its final occupancy. Distant choruses of *Hyla gratiosa* could be heard calling from Tucker Pond on the other side of Putnam Prairie, beginning on March 3. They called each night for the next four days, including the night the frog disappeared. The choruses fell silent when air temperatures fell to near freezing during a late season cold front that moved through north Florida on 8 March. The abandoned burrow measured 7 cm in length and had a maximum depth of 4 cm. The burrow was checked daily for the 20 days following the frog's departure, but the frog failed to return.

LEPTOPELIS ULUGURUENSIS (NCN). **DIET**. While conducting research in the Uzungwa Scarp Forest Reserve (Kilombero District, Udzungwa Mountains, Tanzania), we collected data on the diet of *Leptopelis uluguruensis*, a treefrog endemic to Usambara, Uluguru, and Udzungwa mountain forests in Tanzania (Schøtz 1999. Trefrogs of Africa. Editions Chimaira, Frankfurt am Main. 350 pp.). Sampling was conducted in closed canopy forest in the Kiwege Valley at ca. 850 m asl (UTM 36L0829714; 9070938) from 22–25 August 2004, during the dry season. In the region there had been no rainfall for at least 10 days before and during the study period. Treefrogs were found by night on vegetation surrounding Kiwege stream up to 2 m above ground. Thirty-nine *Leptopelis uluguruensis* (21 males and 18 females and/or juveniles) were stomach flushed (Fraser 1976. Ecology 57:238–251). Males were identified by the presence of blue color on the throat (Schøtz 1999, *op. cit.*). Treefrogs were considered to have empty stomachs if no prey were obtained after two consecutive stomach flushings. Animals were released at the capture site with the exception of voucher specimens preserved in 70% ethanol and deposited in collections of the Museo Tridentino di Scienze Naturali (Trento, Itlay). Prey items were preserved in 70% ethanol and later identified under a dissecting microscope in the laboratory. Prey was obtained from 6 males and 6 females or juveniles (31% of the sample); the mean number of prey per stomach was 1.3 (Table 1). Plant material was also present and consisted of leaf remains. The high percentage of treefrogs with empty stomachs and the low diversity of prey taxa was probably a consequence of the reduced activity of treefrogs and forest arthropods during the study period.

TABLE 1. Diet of *Leptopelis uluguruensis* from the Kiwege Valley, Uzungwa Scarp Forest, Tanzania.

MANTIDACTYLUS MAJORI (NCN). **MALE EGG GUARDING.** Among the endemic Malagasy frogs of the family Mantellidae, the genus *Mantidactylus* is characterized by a wide variety of reproductive modes. In all species, as far as known, eggs are initially deposited outside of the water. Few data are available on reproduction of species in the subgenus *Ochthomantis*, except that they live along streams, mainly in rainforest, and have

FIG. 1. Adult male *Mantidactylus majori* guarding a clutch of eggs at Maharira Forest, Ranomafana, Madagascar, 24 January 2004.

specialized tadpoles with reduced keratinized parts of the oral disk (Blommers-Schlösser 1979. Beaufortia 29:1–77). On 24 Jan 2004, ca. 21 h, we observed *Mantidactylus (Ochthomantis) majori* on a clutch of 16 pigmentless eggs ca. 2.5–3 mm in diameter. The clutch was about 150 cm above the water of a small, slow-moving stream (ca. 3 m in width), on a leaf of a tall bush (Fig. 1), at Maharira Forest, 21°19.547'S, 47°24.147'E, ca. 1250 m elev., Ranomafana National Park, Madagascar. Upon capture we verified that the species was an adult male by its distinct femoral glands. Unfortunately it managed to escape and therefore could not be preserved. The finding is remarkable because *Ochthomantis* belong to a clade of stream-dwelling *Mantidactylus* that usually deposit their eggs on the ground, next to water bodies, whereas egg-deposition on leaves overhanging the water is only known from the phylogenetically distant subgenera *Blommersia, Guibemantis,* and *Spinomantis* (Glaw and Vences 1994. A Fieldguide to the Amphibians and Reptiles of Madagascar, 2nd ed. Vences and Glaw, Köln. 480 pp.). Although females of the latter three subgenera are known to remain, after egg deposition, on their clutches for a short time, usually of several minutes to hours, only in a few species of *Mantidactylus (M. argenteus, M. bicalcaratus, M. punctatus)* is male egg guarding known, in some cases at least until late phases of embryonic development and probably until their hatching (Glaw and Vences 1994, *op. cit.*; Lehtinen 2003. J. Herpetol. 37:766–768). Our data for *M. majori* confirm unpublished observations on this species mentioned in Lehtinen (2003, *op. cit.*) and highlight the plasticity of evolution of reproductive modes in the genus *Mantidactylus,* stressing the need for a reliable phylogenetic hypothesis to understand the evolution of life-history traits in mantellids.

PHRYNOHYAS RESINIFICTRIX (Amazon Milky Frog). **ADVERTISEMENT CALL.** *Phrynohyas resinifictrix* is known to utilize water-filled tree cavities as egg deposition sites. This large tree frog inhabits primary rain forest and old growth secondary forest in Brazil, Colombia, Ecuador, Guiana, and Peru. Water-filled tree cavities serve as ideal sites for ovipositioning and refuge, and as a means by which males can greatly amplify their three to five note bark-like advertisement call. When calling, males often respond to many other sounds by repeating the advertisement call. The advertisement call of *Phrynohyas resinifictrix* (Fig. 1), was recorded on 2 Jan 2000 at 2115 h in old-growth secondary rainforest at the Madre Selva II Biological Reserve in Loreto, Peru (3°37'2"S, 72°14'8"W); when air temperature was 25°C. The location of the specimen was revealed by its advertisement call. During one instance, the specimen ended its advertisement call before it was located. More vocalizations were elicited by imitating the frog's simple three note call. Upon reaching the tree where the frog was hiding, a final series of imitation calls were made. Instead of responding with the typical *BONK-BONK-BONK,* the frog performed

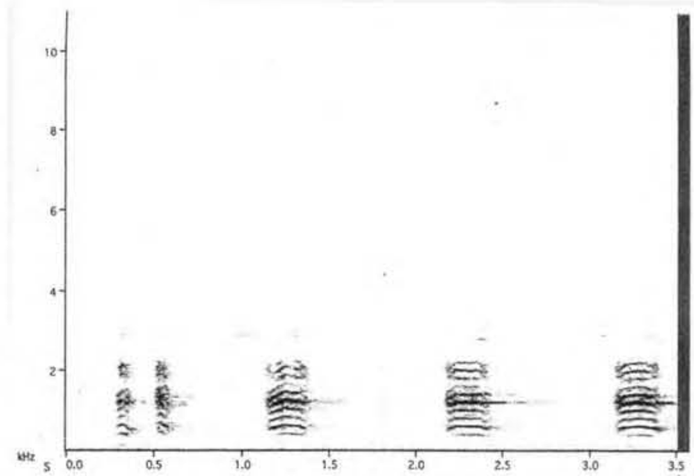

FIG. 1. A spectrographic analysis of an advertisement call from a male *Phrynohyas resinifictrix*. Loreto, Peru. 25°C.

a low pitched, two-note chuckle followed by a lower pitched *whhrrr*. The specimen (42 mm SVL) occupied an ooze-filled, stagnant pool ca. 20 cm deep in the axis of a tree ca. 1.5 m above the ground. Recordings were made in the field using a Marantz ™ PMD 430 magnetic tape recorder and a Radio Shack ™ Dynamic Unidirectional microphone. The call was analyzed using CANARY 1.2.1 (Cornell Bioacoustics station).

Submitted by **CARL J. FRANKLIN**, Amphibian and Reptile Diversity Research Center, The University of Texas at Arlington, Department of Biology, Arlington, Texas 76019, USA; e-mail: Franklin@uta.edu.

PHRYNOHYAS VENULOSA (Veined Treefrog). **REPRODUCTION**. In Trinidad, choruses of *P. venulosa* have been reported from June to December (Kenney 1969. Studies on the Fauna of Curacao and Other Caribbean Islands 29:1–78) and generally occur after periods of heavy rain (Murphy 1997. Amphibians and Reptiles of Trinidad and Tobago. Krieger Publ. Co. 245 pp.). Here we report early breeding that occurred in late May, at the end of the dry season. On 30 May at 0900 EST, we heard several *P. venulosa* calling from exposed sites at the base and top of a small waterfall that was approximately 0.25 km E of our base camp at Petit Tacaribe on the northern coast of Trinidad (10°47'48"N, 61°12'33"W; elev. 15 m). The waterfall had a small pool of water (ca. 2 m diam, and 2–10 cm deep) at its base that was lined with loose rocks. As we approached, several adult frogs scattered and hid amongst the rocks. In the pool, we discovered thousands of eggs and dozens of tadpoles. We caught and preserved 16 tadpoles and determined their stages of development. The average Gosner stage (GS) of development for these individuals was 27.4 (Gosner 1960. Herpetologica 16:283–190), with tadpoles occurring in developmental stages ranging from GS 26 through GS 29 (GS 26, N = 2; GS 27, N = 7; GS 28, N = 6; GS 29, N = 1). These specimens were deposited into the natural history collection at Mercer University, Macon, Georgia as MU 121.

Our observation indicates the *P. venulosa* has the capacity to initiate breeding outside of the traditional wet season if sufficient water is available. Prior studies of this species indicate that hatch-

ing occurs within 24 h of oviposition at GS 20, with individuals typically requiring 6 weeks to complete metamorphosis (Kenney 1969, *op. cit.*). Thus, the collection of tadpoles at GS 26–29 indicates that breeding at the waterfall had occurred several days prior to our observation.

PHRYNOHYAS VENULOSA (Veined Treefrog). **PREDATION**. Arthropod predation upon small vertebrates has been observed in a variety of aquatic and terrestrial systems (McCormick and Polis 1982. Biol. Rev. Camb. Philos. Soc. 57:29–58). Although ecological interactions between large spiders and frogs have been empirically investigated (Formanowicz et al. 1981. Herpetologia 37:125–129; Moore and Townsend 1998. Oikos 81:329–336; Rubbo et al. 2003. J. Zool. Lond. 261:1–5), there have been relatively few observations of predation by crustaceans upon amphibians or reptiles (Voris and Jeffries 1995. J. Trop. Ecol. 11:569–576; Maitland 2003. J. Crust. Biol. 23:241–246). On Tobago, predation by amphibious Manicou Crabs, *Eudaniela garmani,* upon three species of small terrestrial snakes has been reported (Maitland 2003, *op. cit.*). On Trinidad, predation by crabs upon two species of frogs, *Hyla minuta* and *Physalaemus pustulosus*, has also been observed (Murphy 1997. Amphibians and Reptiles of Trinidad and Tobago. Krieger Publish. Co. 245 pp.). Here, we describe predation by Manicou Crabs on adult *P. venulosa* in Trinidad.

On 30 May 2003 at 0900 EST, we discovered two adult *P. venulosa* with severe leg injuries and a partially eaten carcass at the base of a small (2 m high) waterfall that was ca. 0.25 km E of Petit Tacaribe on the northern coast of Trinidad (10°47'48"N, 61°12'33"W; elev. 15 m). The waterfall had a relatively slow moving, small stream of water passing through it and a small pool of water (ca 2 m diam x 2–10 cm deep) at its base. The waterfall and the streambed were lined with large, loose rocks.

On our approach to the waterfall, we observed several adult frogs scatter among the rocks. One individual was missing its left rear leg below the femur and was bleeding from the wound, while the left hind foot of another frog was broken and connected to the ankle by a small amount of muscle and skin. Within 1 m of the pool of water, we found a partially eaten frog that was missing the skin and most of the muscle from the hind legs and dorsum. In the crevices between the rocks, we observed several large Manicou Crabs (70–100 mm carapace width). We captured the injured frog (93.03 mm SVL) with the missing leg (USNM 561850).

The injuries of the frogs are consistent with those that can be inflicted by the large chela of adult Manicou Crabs. The condition of the carcass is also consistent with that reported for prey following feeding by Manicou Crabs (Maitland 2003, *op. cit.*). Our observation indicates that large, terrestrial crabs might be important predators of adult amphibians on Trinidad and Tobago as well as other areas where these crustaceans are known to occur (e.g., northern Venezuela).

Submitted by **VICTOR R. TOWNSEND, JR.**, Department of Biology, Virginia Wesleyan College, 1584 Wesleyan Drive, Norfolk/Virginia Beach, Virginia 23502, USA (e-mail: vtownsend@vwc.edu); and **MICHAEL K. MOORE**, Department of Biology, Mercer University, Macon, Georgia 31207, USA.

PLEURODEMA BUFONINA (Gray Four-eyed Frog) and ***PLEURODEMA THAUL*** (Chile Four-eyed Frog). **OOPHAGY**. Oophagy is a common form of cannibalism in amphibians, most commonly practiced by tadpoles and less often by adults (Crump 1992. *In* Elgar and Crespi [eds.], Cannibalism: Ecology and Evolution Among Diverse Taxa. Oxford Univ. Press). In this note we report the first observation of oophagy in tadpoles of the Patagonian anurans *Pleurodema bufonina* and *P. thaul*. On 15 Nov 2003 during a journey across the Bernal stream (41°06'S 71°10'W), near San Carlos de Bariloche city airport (Rio Negro Province, Argentina) I found several ponds with high densities of *P. bufonina* tadpoles. In these ponds I observed a group of tadpoles feeding on eggs (Gosner Stages 16–18) of the same species. On 28 Dec 2004 between 1400–1800 h, I transferred three segments of a gelatinous string, each containing 50 eggs, into three small ponds (1, 1.2, and 1.6 m^2) with a high density of Gosner Stage 36–39 tadpoles, temperature was 25°C (± 3°, range 20–26°C). I observed the behavior of tadpoles in one pond for four hours. About 10 minutes after I placed the eggs into the pond, tadpoles began to move toward the eggs, and after 30 minutes there were 25 tadpoles feeding on the eggs. After 4 h, 70% of the eggs still survived. Oophagy in *P. bufonina* tadpoles has been observed under natural conditions by Weigandt (pers. comm.), and seems to occur frequently.

On 28 Dec 2004, during surveys in a permanent pond ca. 5 km W of San Carlos de Bariloche city, I observed *P. thaul* tadpoles (Gosner Stages 38–40) feeding on eggs of the same species. The eggs were Gosner Stages 18–20, and some were colonized with fungus.

Pleurodema bufonina and *P. thaul* reproduce from early spring through early summer in temporary and semi-permanent environments, therefore eggs and tadpoles in different developmental stages often share the same pond. Additional observations of oophagy in these species are important to help in the understanding of oophagy as source of mortality and its influence in the choice of oviposition sites.

RANA BERLANDIERI (Rio Grande Leopard Frog). **SALINITY TOLERANCE**. Few species of amphibians are typically found in marine-influenced habitats (Shoemaker and Nagy 1977. Ann. Rev. Physiol. 39:449–71). With few exceptions (e.g., *Rana sphenocephala* [Bockstanz and Cannatella 2000. http://www.zo.utexas.edu/research/txherps/]), North American ranids are also not recorded in coastal, marine-influenced habitats. Bently and Schmidt-Nielsen (1971. Comp. Biochem. Physiol. A 40:547–48) found that exposure to seawater resulted in death of post-metamorphic *Rana pipiens* (*sensu lato*).

During periodic marine fisheries related surveys, I noted the presence of post-metamorphic *R. berlandieri* at the Port Mansfield State boat ramp, 26°33'24"N, 97°25'44"W, Willacy County, Texas. This site is in the Port Mansfield harbor in the Lower Laguna Madre, a hypersaline lagoon. Frogs were observed (N = 100+) beneath the pier (on land) and beneath bait tanks inside the bait shop. In July, a sample was captured (N = 5), identity confirmed, measured (mean SVL 35 mm, range 30–50 mm), and released. All frogs observed were in this size range and probably represent a single cohort. The frogs were initially noticed on 21 July 2004, noted again 6 August, 21 August, and 1 Sept but were gone by 20 Sept 2004, persisting almost two months. Salinities were measured with a hand-held refractometer (39 o/°° on all dates). Frogs were actively foraging and frequently made excursions into sunlit areas to feed on insects attracted to rotting vegetation (*Halodule* sp.) and fish carcasses. Although frogs were not observed sitting in seawater, they were sitting upon piles of *Halodule* within 0.1 m of the waters edge. Frogs beneath the pier were frequently moistened by wave action and by water sluicing off boats and trailers being pulled out at the ramp. These observations suggest that marine-mediated habitats are not absolute barriers to certain ranid activities and movements through these less than optimal habitats.

RANA BOYLII (Foothill Yellow-legged Frog). **COLORATION.** *Rana boylii* has been characterized as possessing variable amounts of yellow in the groin and the lower surfaces of the hind limbs (Zweifel 1955. Univ. California Publ. Zool. 54:207–292; Stebbins 2003. A field guide to western reptiles and amphibians. 3rd ed, revised, Houghton Mifflin Co., Boston. 544 pp.). Among western North American *Rana* belonging to the *Rana boylii* group (*sensu* Macey et al. 2001. Mol. Phylog. Evol. 19:131–143), *R. aurora*, *R. draytonii*, *R. luteiventris*, *R. muscosa*, and *R. pretiosa* have been reported to have either orange or red on ventral body surfaces in moderate to high frequencies in some or all of their known populations (Altig and Dumas 1972 [*sic.* 1974]. Cat. Am. Amphib. Rept. 160.1–160.4; Stebbins, *op. cit.*). Zweifel (*op. cit.*) indicated that some individuals of *R. boylii* had some red pigment on the dorsolateral folds, but made no mention of orange or red pigment on lower body surfaces. Hence, we report here on color morphs of *R. boylii* that possess orange or red on lower body surfaces from three localities in California.

One of us (MRJ) made observations on over 1000 postmetamorphic *R. boylii* from Salt Creek on a reach 3–8 km W of Newville (Glenn Co.; 39°47'58"N, 122°33'34"W; elev. 200 m to 39°47'00"N, 122°35'17"W; elev. 265 m) and on Thomes Creek, ca. 1.6 km SW of Paskenta (Tehama Co.; 39°52'22"N, 122°33'30"W; elev. 229 m) between March and November 1981, and we both made observations on 24 individuals from Del Puerto Creek at Frank Raines Regional Park, 25.4 km (by road) W of Interstate 5 (Stanislaus Co.; 37°25'16"N, 121°22'23"W; elev. 332 m).

About 5% of the *R. boylii* from Salt and Thomes Creeks had orange or red pigment on the undersurfaces of the hindlimbs, and all individuals with this coloration were uniformly the largest females. Individuals with orange were at least three times as frequent as those with red, which was of a hue intermediate between brick and scarlet. At Del Puerto Creek, 22 (10 females, 10 males, and 2 subadults; range: 28–47.5 mm SVL) of 24 *R. boylii* possessed a citrus orange color on the medial three-fourths of the lower surfaces of the thighs. The orange varied in intensity from bright to faded, being much more developed in the largest adults, and was clearly distinguishable from the more typical lemon-yellow pigment (*fide* Zweifel, *op. cit.*) on the lateral fourth of the lower surfaces of the thighs, the groin, the calves, and the back of the knees. All except four individuals having orange on their thighs had an orangish tinge on their feet, and five of those individuals also had orange on the edges of the belly or in the axillae.

These observations are significant because increasing numbers of misidentified *R. boylii* have been reported in recent years based solely on visual color observations (MRJ, unpubl. data). Notably, cases of unusually large, orange or red-colored *R. boylii* have been reported to agency personnel as representing the federally-listed *R. draytonii* that were later recanted after visual inspection of photographs taken of these frogs. These observations are also significant beyond simply documenting the variation found in *R. boylii* since possession of orange or red coloration seems to vary ontogenetically. The related *R. aurora* and *R. draytonii* are well known to show a marked yellow to red ontogenetic transition (Stebbins, *op. cit.*). Ontogenetic color transition helped define relationships among some dendrobatid frogs (Myers et al. 1978. Bull. Am. Mus. Nat. Hist. 161:307–366), so it may be useful in assessing the phylogenetic relationship of *R. boylii* within the *R. boylii group*, whose position has been contested on the basis of at least two contrasting hypotheses (Green 1986. Syst. Zool. 35:283–296; Hayes and Krempels 1986. Copeia 1986:927–936; Macey et al., *op. cit.*).

RANA BOYLII (Foothill Yellow-legged Frog). **PREDATION.** Mallard Ducks (*Anas platyrhynchos*) are known to consume ranid frogs; yet to our knowledge, only three ranid species have been reported as prey: *Rana temporaria* (Mjelstad and Saetersdal 1989. Fauna Norvegica Series C 12:47–48), *R. sylvatica* (Eaton and Eaton 2001. Can. Field-Nat. 115:499–500), and *R. aurora* (Hayes and Rombough 2004. Herpetol. Rev. 35:375–376). Here, we add a fourth ranid species, *Rana boylii*, to the list of *A. platyrhynchos* prey.

We made these observations along the South Santiam River, 10 km E of Sweet Home, Linn County, Oregon (44°40'97"N, 122°56'54"W; elev. 192 m). As described elsewhere (Rombough and Hayes 2004, *op. cit.*), site geology is distinctive. Hard competent tuffs compose a relatively flat bedrock surface within which

seams of softer conglomerates have been eroded into a series of troughs and scour pools. *Rana boylii* occupy the troughs and pools during most of their active season. Observations reported here occurred during oviposition, when adult *R. boylii* are generally more visible than at other times of the year. River width was 100–120 m, and water depth over the flat, about half of which is submerged, averaged 15–20 cm.

During surveys for *R. boylii* egg masses, at 1500 h on 12 June 2003, AMS and CJR observed one *A. platyrhynchos* pair (drake and hen) feeding ca. 70 m away in a bedrock pool. The *A. platyrhynchos* seemed to be probing the pool shallows. As AMS, CJR, and JC approached indirectly over ca. 3 min, the ducks dabbled in the pool, and at least twice appeared to frantically chase prey around the large (30 cm diam) cobbles bordering the pool. Following the second of these chases, the drake was seen to have a prey item in its bill. The drake tilted its head back, attempted to manipulate the prey, then lowered its head behind a rock. At this point, the observers, continuing to approach slowly, were within 50 m, and flushed the hen; the drake subsequently dropped his prey and followed. Minutes later, JC found an injured, adult male (52.5 mm SVL, 15.2 g) *R. boylii* lying upside down in the pool that the *A. platyrhynchos* had vacated. The frog's body was flattened; its head, besides being markedly flattened, had a 3 mm puncture wound located between and just behind the eyes. The head and anterior portion of the frog was covered with small (1–5 mm) lacerations, and the skin and muscle tissue was removed from about half the left forearm (a 10 x 6 mm area). When found, the frog showed faint signs of life (weakly moving its limbs and nictitating membranes); efforts to revive it failed. The frog was preserved and deposited in the herpetology collection at Oregon State University (OSUMNH 11341).

On 22 June 2004 at 0822 h, three *A. platyrhynchos* (two drakes, one hen) were observed foraging intensively in a series of trough pools that held a breeding aggregation of male *R. boylii*. The *A. platyrhynchos* allowed CJR to approach to within 30 m before swimming away. Seven adult male *R. boylii*, all submerged or partially emergent in the shallows at that location, were captured and measured during the hour after the ducks left. Although *A. platyrhynchos* is known to breed downstream, over four years of observation, *A. platyrhynchos* have only been observed in abundance at the site during June (CJR, pers. obs.), coincident with *R. boylii* oviposition.

Mallards are omnivorous, and opportunistically exploit animal food (Nummi 1985. Suomen Riista 32:43–49; Sugden and Driver 1980. J. Wildl. Manage. 44:707–709). Invertebrates represent most animal prey in *A. platyrhynchos* diet, but the comparatively higher digestibility of many vertebrates might account for part of this relative scarcity (see Hayes and Rombough, *op. cit.*); frogs (e.g., *R. temporaria*) are sometimes important as prey (Mjelstad and Saetersdal, *op. cit.*). During some times of the year (e.g., fledging and yolking of eggs), *A. platyrhynchos* are known to seek out higher protein foods (Collias and Collias 1963. Wilson Bull. 75:6–14; Nummi 1993. Can. J. Zool. 71:49–55; Perret 1962. The spring and summer foods of the Common Mallard [*Anas platyrhynchos platyrhynchos* L.] in south central Manitoba. MSc Thesis, University of British Columbia, Vancouver, BC. 82 pp.). In such cases, vertebrates, notably amphibians, might provide an important protein resource.

Animals were handled under a permit from the Oregon Department of Fish and Wildlife.

RANA CATESBEIANA (American Bullfrog). **DIET**. On 6 Nov 2003, a male *Rana catesbeiana* (177.4 g w/o stomach contents, 12.1 SUL, 15.1 cm girth) was discovered dead, floating in a 250 gallon plastic-lined pond in the northern part of Anderson County, Tennessee. Protruding from the frog's mouth were the rear legs and tail of a mammal. Having seen chipmunks in the area, the discoverer assumed the frog had choked to death on a chipmunk. After freezing it, she donated the frog to the Clinton High School ecology class, which performed a necropsy with the following results.

The mammal was a small, 35.5 g, Grey Squirrel (*Sciurus carolinensis*) with body length of 12.3 cm and tail length 7.7 cm. The squirrel was easily removed from the frog's mouth by simply pulling it out. In the process, the stomach inverted, emptying its contents.

Stomach contents (w/o squirrel) weighed 5.2 g, and included: a millipede (*Alpheloria montana*), two small snails, a sunflower seed, the elytra from two beetles (possibly click beetles), small bits of bark and grass, and the wrapper from a "beef log." Although the cause of death was speculated to be choking on the squirrel, another explanation could be cyanide toxicity from the millipede.

We thank Richard Hoffman of the Virginia Museum of Natural History for identifying the millipede, Dr. Edmund Brodie III for discussions, and Virginia Stooksbury for providing the specimen.

RANA CLAMITANS (Green Frog) and ***RANA CATESBEIANA*** (American Bullfrog). **REPRODUCTION.** Green Frogs and American Bullfrogs often share the same habitat. Interactions between the two species are common, but studies have focused mainly on the effect of competition and on predatory interactions (Werner et al. 1995. J. Herpetol. 29:600–607; Hecnar and M'Closkey 1997. Am. Midl. Nat. 137[1]:145–150).

Here I report an instance of mating interaction between the two species. In July 2004, I visited a pond at Basket Wildlife Research Area (Boone County, Missouri, USA). A chorus of *R. clamitans* was well established, and I quickly found a pair of ranids in amplexus, which at first I considered to be *R. clamitans*. However, the pair was composed of a male *Rana clamitans* and a female *R.*

FIG. 1. Male *Rana clamitans* in amplexus with a female *R. catesbeiana*, found in central Missouri.

catesbeiana. Although some American Bullfrogs were calling that night, they were greatly outnumbered by *R. clamitans*, and the resulting high competition for conspecific females may have contributed to the mating mistake of the *R. clamitans* male.

Between-species amplexus may incur several costs for both participants. Besides lost feeding opportunity and increased risk for predation there is also the cost of lost reproductive effort. This is especially severe in the case observed above, since crosses between male *Rana clamitans* and female *R. catesbeiana* produce inviable hybrid offspring (Elinson 1981. Dev. Biol. 81[1]:167–176).

RANA CLAMITANS MELANOTA (Northern Green Frog). **PREDATION**. Crayfish have been known to prey on eggs and larvae of several species of amphibians (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 587 pp.; Axelsson et al. 1997. Amphibia-Reptilia 18:217–228). However, few instances of crayfish preying on adult amphibians exist. Here we report observations of a stream crayfish preying on an adult *R. c. melanota*.

On 18 July 2004 at 1035 h, an adult male *R. c. melanota* (ca. 50 mm TL) was found moving erratically within a mat of aquatic vegetation (ca. 10–20 cm deep) growing in a stream resurgence located at the bottom of a sinkhole entrance to Snail Shell Cave in Rutherford County, Tennessee. Upon further inspection, we observed the frog's left hind leg caught in the left cheliped of a crayfish (*Cambarus* sp. ca. 75 mm TL) that was concealed in the vegetation. The frog repeatedly attempted to free itself by rapidly extending its hindlegs. We observed the interaction for ca. 5 min, when the frog escaped and move ca. 20 cm away from the crayfish. A few seconds later, the crayfish bolted from its position, grasped the frog by its left hind limb once again, and pulled it back towards the vegetation. During the scuffle we noticed that the frog's foot was mangled and nearly half ingested. We observed this interaction for another 5 min before heading into the cave. Research was supported by a grant to BTM from the Tennessee Wildlife Resources Agency (Contract Num. ED-04-01467-00).

TESTUDINES

ACTINEMYS MARMORATA (Western Pond Turtle). **SIZE**. The largest recorded carapace length for *Actinemys marmorata* is a length of 216 mm (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, Peterson Field Guide Series; Jennings and Hayes 1994, Amphibian and Reptile Species of Special Concern in California. California Department of Fish and Game, Sacramento). I captured a male with a 223 mm carapace length and a 193 mm plastron length on 20 August 2003 during a population study at Lake Lagunitas, Mount Tamalpais Watershed, Marin County, California. I measured the straight-line carapace and plastron length by using a caliper. The male was basking on a log before being captured. This specimen represents the largest *Actinemys marmorata* yet recorded. This study was conducted under California Fish and Game Scientific Collection Permit no. 801154-05 and was funded by the Marin Municipal Water District..

Submitted by **PIERRE FIDENCI**, GANDA, 1 Saunders Ave, San Anselmo, California 94960 USA; e-mail: leytensis@mail.com.

APALONE FEROX (Florida Softshell). **PREDATION.** While mainly thought of as piscivores, Bald Eagles (*Haliaeetus leucocephalus*) include reptiles, specifically turtles, and mammals in their diets (Mabie et al. 1995. J. Raptor Res. 29:10–14). Bald Eagles are reported to eat turtles of several species (Clark 1982. J. Field Ornithol. 53:49–51; Mabie et al., *op. cit.*), although the literature is incomplete regarding eagle predation on the family Trionychidae. When trionychid turtles are noted as Bald Eagle prey, the names listed have been limited to group names and genera, with no reference to species (e.g., "soft shell" or "soft shelled" turtles; see Clark, *op. cit.*; Mabie et al., *op. cit.*).

On 16 February 2005 at Lake Nona, Orange County, Florida, I found the shell of an *Apalone ferox* underneath a Bald Eagle nest. The nest was located along the edge of the lake in a wetland in the snag of a large pine tree. The carapace length was ca. 10 cm, but a more accurate measurement was unavailable because of the condition of the shell. The body was decayed, and the carapace had a large gash running across it. The skull of an adult Virginia Opossum (*Didelphis virginiana*) was also found underneath the nest.

Sea Turtles of the World. 81 pp.) did not specify nesting periods for either *E. imbricata* or *C. mydas* in the Mariana Islands and Wiles et al. (*op. cit.*) did not identify nesting areas on Guam. Historical information on Guam nesting sites is presented in Table 1. Identification to species was not recorded, as nesting or hatching was generally not observed and nests or false nests were usually not excavated. Although Guam has apparently never been systematically surveyed specifically for marine turtle nesting activity, it is clear that nesting, albeit at at low levels, has occurred for at least several decades. Based on the records presented here, nesting for both species occurs between March and August in the southern Mariana Islands.

EMYDOIDEA BLANDINGII (Blanding's Turtle). **BODY MASS AND SIZE.** We examined body mass and body size parameters of 37 (17 female, 20 male) adult *Emydoidea blandingii* captured in southeastern (Strafford and Rockingham counties) and central New Hampshire (Merrimack and Hillsborough counties) during the active season (May–November) from 2000 to 2002. We note variations between New Hampshire *E. blandingii* and other populations.

We recorded body mass and size at initial capture. We weighed each turtle to the nearest 5 g, and measured maximum straight-line distances for carapace width (CW), carapace length (CL), plastron width (PW), plastron length (PL), and shell height to the nearest 1 mm with calipers. We counted plastral scute rings to estimate age in *E. blandingii* < 20 years of age (Congdon and van Loben Sels 1991. Can. J. Zool. 69:239–245), and determined sex by presence or absence of plastral concavity and distance from the cloacal opening to the carapacial margin (Ernst et al. 1994. Turtles of the United States and Canada, Smithsonian Institution Press, Washington, D.C.). We categorized turtles 16 years as adults based on the following: 1) we observed reproductive activity in one 18 year-old male and four females (16, 17, 18, 19 years), in addition to several turtles ≥ 20 years-old, and 2) physical traits (e.g., plastral concavity) associated with maturation in males were evident in males 16 years of age. Although we captured three juvenile *E. blandingii* (10 years, 158 mm PL; 7 years, 107 mm PL, 8 years, 108 mm PL), we captured no turtles 11 to 15 years of age. We used a Mann-Whitney U test to determine whether our population exhibited evidence of sexual dimorphism.

We detected differences in body measurements between the sexes. Male *E. blandingii* exhibited wider (range: 133–159 mm) and longer (range: 205–240 mm) carapaces than females (CW, range: 122–153 mm, $p < 0.001$; CL, range: 181–199 mm, $p < 0.001$). We did not find significant differences between other morphological parameters, although male *E. blandingii* frequently exhibited heavier body mass (range: 825–1775 g) and wider plastrons (103–126 mm) than females (mass, range: 1050–1900 g, $p = 0.19$; PW, range: 97–123 mm, $p = 0.14$). In addition, female *E. blandingii* frequently exhibited higher shells (range: 73–90 mm) than males (range: 72–90 mm, $p = 0.09$). Plastron length did not differ significantly between the sexes (female, range: 175–227 mm; male, range: 184–226 mm, $p = 0.78$).

We detected sexual shape dimorphism in our New Hampshire populations. Sexual size and shape differences between sexes have been shown in other populations. Females frequently exhibit wider plastrons and higher shells for a given carapace length than males (sexual shape dimorphism) and males often exhibit longer plastrons and heavier body mass than females (sexual size dimorphism; Congdon and van Loben Sels 1991, *op. cit.*; Germano et al. 2000. Chelonian Cons. Biol. 3:611–617; Graham and Doyle 1979. J. Herpetol. 13:125–127; Pappas et al. 2000. Chelonian Cons. Biol. 3:557–568). However, in some *E. blandingii* populations sexual size or sexual shape dimorphism is not evident (Joyal et al. 2000. Chelonian Cons. Biol. 3:580–588; Rowe 1992. Can. J. Zool. 70:1690–1965).

New Hampshire *E. blandingii* body measurements reported here are similar to those from other populations in the eastern portion of its range (Maine: Joyal et al. 2000, *op. cit.*; Massachusetts: Graham and Doyle 1979, *op. cit.*; Nova Scotia, Canada: McMaster and Herman 2000. Chelonian Cons. Biol. 3:602–610), but are generally larger than those from the Midwest and Great Lakes Region (southeastern Michigan: Congdon et al. 1986. Amer. Midl. Nat. 115:165–173; southwestern Michigan: Gibbons 1968. Can. J. Zool. 46:288–290; Ontario, Canada: MacCulloch and Weller 1988. Can. J. Zool. 66:2317–2319). In western Nebraska, where sexual shape dimorphism was most apparent, CL and body mass of females were smaller and males were similar to those of New Hampshire (Germano et al. 2000, *op. cit.*). *Emydoidea blandingii* in north-

western Minnesota were substantially larger than any reported elsewhere (Sajwaj et al. 1998. Final Rept. Non-game Wildlife Office, MN Department NR, Brainerd, MN).

This work was supported by the New Hampshire Fish and Game Department and the New Hampshire Department of Environmental Services with funds from the Environmental Protection Agency.

Submitted by **ROBIN J. INNES, KIMBERLY J. BABBITT,** Department of Natural Resources, University of New Hampshire, Durham, New Hampshire 03824, USA (e-mail: kbabbitt@cisunix.unh.edu); and **JOHN J. KANTER,** New Hampshire Fish and Game Department, Concord, New Hampshire 03301, USA.

GOPHERUS POLYPHEMUS (Gopher Tortoise). **JUVENILE USE OF GOPHER TUNNEL.** Mammals occasionally make use of Gopher Tortoise burrows (Frank and Lips 1989. Florida Field Nat. 17:20–22) and in some instances they may be closely associated with the burrows (e.g., Jones and Franz 1990. Florida Field Nat. 18:45–68). However, to our knowledge, only a single record exists of Gopher Tortoises using structures excavated by mammals, the record being a description of an adult Gopher Tortoise nesting in a pocket gopher (*Geomys pinetis*) mound (Epperson and Wendland 1997. Herpetol. Rev. 28:87).

On 2 November 2004 at 1001 h, we visited the burrow of a hatchling tortoise that had emerged from its nest on 5 September 2004 (SLCL = 53.08 mm, SLPL = 53.43 mm, mass = 38.06 g), and fitted with a radio-transmitter and released on 6 September 2004 at the Joseph W. Jones Ecological Research Center in Baker County, Georgia (USA). The hatchling had been tracked to its burrow the previous day at 1420 h and no disturbance had been observed. However, on 2 November, the burrow was found to have fresh dirt filling the entrance and emerging onto the apron. We radio tracked the hatchling to an area ca. 11.6 m straight line distance from its burrow and the signal was coming from below ground. We excavated the area to determine the status of the hatchling and it was located alive, ca. 37 cm below ground in a pocket gopher tunnel. Approximately two minutes after excavation, a pocket gopher began to back-fill the exposed portion of the tunnel. Eight pocket gopher mounds were observed within about 5 m of the location. The habitat surrounding the site consisted primarily of Wiregrass (*Aristida beyrichiana*) with sandy soils, and an open Longleaf Pine (*Pinus palustris*) canopy. From our observations, we conclude that a burrowing pocket gopher intersected the tortoise burrow and the tortoise proceeded along the newly constructed, adjoining pocket gopher tunnel. Over the previous 54 days, this individual had been tracked 26 times and had traveled a total straight line distance of only 10.1 m as compared to this recorded movement of more than 11 m. Juvenile Gopher Tortoises do possess the ability to dig out of occluded burrows (Diemer 1992. J. Herpetol. 26:158–165), so pocket gopher activity would not necessarily lead to increased tortoise mortality.

Submitted by **DAVID A. STEEN, GABRIEL J. MILLER, SEAN C. STERRETT,** and **LORA L. SMITH**, Joseph W. Jones Ecological Research Center, Route 2, Box 2324, Newton, Georgia 39870, USA; e-mail (DAS): David.Steen@jonesctr.org.

KINOSTERNON BAURII (Striped Mud Turtle). **SIZE AND REPRODUCTION.** *Kinosternon baurii* occurs in the floodplain swamp along the lower Apalachicola River in Franklin and Gulf Cos., Florida (Ewert et al. 2004. Herpetol. Rev. 35:80). Two of eight females from the previously reported sample were larger than any documented for any *K. baurii* or *K. subrubrum* (Conant and Collins 1998. A Field Guide to Reptiles & Amphibians, Eastern and Central North America, third ed., expanded. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.). The longest (UF 143962), found 18 August 1991 (max. CL = 138 mm, max PL = 129 mm, CW = 95 mm, non-gravid mass = 398.8 g) contained 7 eggs (RCM = 0.134), and the heaviest, found 7 May 1991 (max CL = 135 mm, max PL = 128 mm, CW = 97 mm, non-gravid mass = 401.0 g) contained 6 eggs (RCM = 0.101). Both females were on land, presumably to nest, near the upstream end of Forbes Island in the Apalachicola River (29.9451°N, 85.0166°W, WGS84/NAD83).

In all, we found seven gravid females, two intact nests, and several eggshells from depredated nests. Mean clutch size was 4.7 eggs (range 3–7, N = 9). Mean egg size was 6.8 (range 4.6–8.1) g and 29.9 (range 25.0–32.3) mm x 18.9 (range 17.0–20.4) mm. One larger viable egg produced in captivity was 8.6 g, 34.5 x 19.4 mm, and two depredated eggshells were ~35 mm long. Five gravid females were nesting or on land during mid-late mornings 7–17 May and 16–18 August, which occurred within brief periods of field work (~12 d April–May, ~5 d August). Thus, nesting could occur from spring into the late summer.

These data suggest that locally, at least, eastern *Kinosternon* more closely approach in body size several species from west of the Mississippi River (review in Iverson 1991. Herpetol. Monogr. 5:1–27) than prior measurements had indicated. Although the sample size is small, *K. baurii* from along the lower Apalachicola River appear to lay larger clutches of larger eggs than do populations in peninsular Florida (Wilson et al. 1999. Copeia 1994:958–968; Meshaka and Blind 2001. Chelon. Cons. Biol. 4:75–80).

MAUREMYS RIVULATA (Balkan Terrapin). **ENDOPARASITES.** *Mauremys rivulata* is a freshwater turtle that ranges through southeastern Europe, Bulgaria, western Turkey, coastal Syria, Lebanon and Israel (Ernst and Barbour. 1989. Turtles of the World, Smithsonian Institution Press, Washington, D.C. 313 pp). To our knowledge there are no reports of helminths from *M. rivulata*. The purpose of this note is to report two species of Digenea and two species of Nematoda in *M. rivulata* from Turkey.

Sixteen *M. rivulata* (mean carapace length = 17.9 cm ± 3.1 SD, range: 9–24 cm) were collected in 1996, 1999–2003 in Turkey. Eleven were from Görükle (40°15'N, 28°49'E), four were from Kayapa (40°10'N, 28°52'E), one was from Nilufer Çayi (40°16'N, 29°02'E). Terrapins were sacrificed with an overdose of sodium pentobarbital. The esophagus, stomach, small and large intestines were opened and examined for helminths. Digeneans were fixed

in 70% ethanol, stained with iron-carmine and studied as whole mounts. Nematodes were fixed in 70% ethanol, cleared in a drop of glycerol and examined as wet mounts. Voucher terrapins were deposited in the Department of Biology, Uludag University, Bursa, Turkey. Helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland.

Found in the large intestines were two species of Digenea, *Patagium lazervai* (prevalence: number infected/sample examined x 100 = 6%; mean intensity $\pm$ 1 SD: mean number helminths per infected individual = 14) and *Telorchis stossichi* (prevalence = 88%; mean intensity = 39.6 $\pm$ 66; range = 1–198) and two species of Nematoda in the small intestines, *Falcaustra armenica* (prevalence = 69%; mean intensity = 2.5 $\pm$ 16.4, range = 1–53) and *Serpinema microcephalus* (prevalence = 81%; mean intensity 12.8 $\pm$ 13.8; range = 1–45). Voucher helminths were deposited in the United States National Parasite Collection as: *Patagium lazervai* (USNPC 94734), *Telorchis stossichi* (USNPC 94735), *Falcaustra armenica* (USNPC 94736), *Serpinema microcephalus* (USNPC 94737).

Both *Patagium lazervai* and *Telorchis stossichi* were originally described from *E. orbicularis* collected in Armenia and Europe, respectively, and until now were not known from any other host. *Falcaustra armenica* has been reported from *Emys orbicularis* and *Mauremys caspica* from Macedonia and Russia and *Serpinema microcephalus* has been reported from *E. orbicularis* and *M. caspica* from Europe, Russia and North Africa and the lacertid lizard, *Eremias arguta* from Russia (see Baker 1987. Mem. Univ. Newfoundland, Occas. Pap. Biol. 11:1–325). *Mauremys rivulata* represents a new host record for *Patagonium lazervai, Telorchis stossichi, Falcaustra armenica* and *Serpinema microcephalus*. Turkey is a new locality record for each species.

PSEUDEMYS GORZUGI (Rio Grande River Cooter). **MAXIMUM SIZE.** On June 5, 2004, while collecting ecological data in the Devil's River, Val Verde County, Texas, we collected a female *P. gorzugi* with a carapace length of 372 mm, a plastron length of 335 mm, and a total weight of 5600 g. The individual was observed on the river bottom and was hand collected. This is the largest specimen of this species ever collected based on published literature (Ward 1984. Special Publications The Museum Texas Tech University. 21:31; Ernst 1990. Cat. Amer. Amph. Rept. [461]:1–2). This animal was marked prior to release by drilling holes in her marginal scutes for permanent identification. This allowed incorporation of this individual within a long-term mark and recapture study being conducted on this species in Texas by MRJ Forstner and JR Dixon. All work conducted is allowed by Texas Parks and Wildlife Department permit number SPR-0102-191 to MRJF.

Submitted by **JAMES STOUT, LINDLEY BAILEY, JAMES R. DIXON**, and **M. R. J. FORSTNER**, Department of Wildlife and Fisheries Sciences, Texas A&M University, College Station, Texas 77843, USA; e-mail (JS): jimstout@tamu.edu.

TERRAPENE ORNATA (Ornate Box Turtle). **DIET**. On 20 June 2004, we observed a female *Terrapene ornata* eating the skin and entrails of an adult *Bufo cognatus* (Great Plains Toad) killed on the road the previous night. The turtle was located on a gravel road approximately 1/10 of a mile inside the gate at the Mescalero Sands Study Area, Chavez County, New Mexico. *T. ornata* are omnivorous and known to consume carrion (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 578 pp.; Kolbe 1998. Herpetol. Rev. 29:235; Legler 1960. Univ. Kansas Publ. Mus. Nat. Hist. 11[10]:527–669) including remains of venomous snakes (Jensen 1999. Herpetol. Rev 30:95). A captive *T. ornata* was observed eating *Spea multiplicata* tadpoles; however an adult *S. multiplicata* was released after capture, followed by the turtle wiping its mouth with its forepaw (Norris and Zweifel 1950. Nat. Hist. Misc. 58:1–4). In the case reported here, the turtle consumed the remains of an anuran species known to have significant skin toxicity.

LACERTILIA

AMEIVA AMEIVA (Giant Ameiva). **PREDATION.** The teiid *Ameiva ameiva* is among the most broadly distributed Neotropical lizards, occurring from Panama to south-central Brazil (Vitt and Colli 1994. Can. J. Zool. 72:1986–2008). Available records of predation on *A. ameiva* are by snakes (*Crotalus durissus*: Santos and Germano 1996. Herpetol. Rev. 27:143; and *Oxybelis fulgidus*: Fischer and Gascon 1996. Herpetol. Rev. 27:204). Here we add to the predator set known for *A. ameiva* with a report of predation by the Burrowing Owl, *Athene cunicularia* (Aves: Strigidae) from southeastern Brazil.

At 2100 h (nighttime) on 20 August 2003, we observed an *A. cunicularia* handling a lizard along an unpaved road that crosses an area of pristine "campo sujo" (shrubby grassland) at Itirapina Ecological Station (IES; 22°12'30"S, 47°54'45"W [datum: Corrego Alegre]); elev. 760 m), municipality of Brotas, State of São Paulo. On our approach, the owl flew off, leaving the lizard on the ground. Examination revealed the lizard completely decapitated with a few wounds on the body. It was an adult male *A. ameiva* (estimated at 93 mm SVL; 142 mm tail length). *A. cunicularia* is known to use head attack sometimes involving decapitation on dangerous snakes (see Valdujo and Nogueira 2000. Herpetol. Rev. 31:45; Martins et al. 2001. Herpetol. Rev. 34:147–148).

Considering the reported diurnal habit of *A. ameiva* (Vitt and Colli, *op. cit.*), this predation event is interesting. As *A. ameiva* generally occupies concealed locations in crevices or burrows at night (Vitt and Colli, *op. cit.*), this report suggests that either the lizard was resting at an exposed location or was active at an atypi-

cal time. Regardless of the alternative, this event indicates that *A. ameiva* might sometimes be vulnerable to nocturnal predators such as mammal and birds.

The *A. ameiva* voucher (MZUSP 94110) is deposited in the Museu de Zoologia da Universidade de São Paulo. D. Zanchetta and Instituto Florestal staff facilitated our IES fieldwork. We thank Jivanildo P. Miranda, Cristiano Nogueira, and Marc P. Hayes for lizard identification and/or suggestions on the manuscript. FAPESP (00/12339-2) and CNPq (470621/2003-6) provided funding. This is publication Number 22 of the project Ecology of the Cerrados of Itirapina.

Submitted by **ALEXANDRO M. TOZETTI** (e-mail: mtozetti@uol.com.br), **NORBERTO HULLE** (e-mail: bhulle@ib.usp.br), Departamento de Ecologia, Instituto de Biociências, Universidade de São Paulo, C.P. 11461, 05508-900, São Paulo, SP, Brazil, and **VICTOR VETORAZZO** (e-mail: razlogan@yahoo.com.br) student of Laboratório de Herpetologia, Instituto Butantan, Av. Vital Brazil, 1500, 05503-900, São Paulo, SP, Brazil.

AMPHISBAENA IBIJARA (NCN). **PREDATION.** Amphisbaenians are secretive, so little is known of their natural history. *Amphisbaena ibijara*, a small amphisbaenian (98–249 mm total length; Rodrigues et al. 2003. Phyllomedusa 2:21–26) endemic to the municipality of Urbano Santos (3°12'28"S, 43°21'12"W [datum: South America 69]; elev. 41 m), State of Maranhão, northeastern Brazil is no exception. To date, the only recorded predator is a coral snake, *Micrurus ibiboboca* (Gomes et al. 2005. Herpetol. Rev. 36:170). Here, we add to the predator list with an observation of predation by the colubrid snake *Apostolepis pymi*.

At 1700 h on 10 March 2004, while excavating in gallery forest habitat, we found an adult *A. pymi* (575 mm SVL, 41 mm tail length; 29 g) that was buried in soil ca. 12 cm deep. The snake was accidentally severed, exposing its stomach containing prey. Dissection of the preserved snake revealed the hindquarters of an adult *A. ibijara*. The amphisbaenian was largely digested, with only a 12.9 mm tail remnant remaining.

Apostolepis pymi is fossorial and known to feed on small snakes and amphisbaenians (Cunha and Nascimento 1978. Publ. Av. Bol. Mus. Para. Emílio Goeldi, Sér. Zool., Belém, 31:1–218), but this report adds a new species to its prey list.

We deposited the snake [IB 72503] in the herpetological collection of the Instituto Butantan in São Paulo, SP. Hebert Ferrarezzi verified the snake's identity.

Submitted by **JERRIANE O. GOMES** (e-mail: jerrianegomes@yahoo.com.br), **FABRÍCIA L. BRITO** (e-mail: fabriciabio@yahoo.com.br), **ADRIANO O. MACIEL** (e-mail: aombiologo@yahoo.com.br), **JOÃO CARLOS L. COSTA** (e-mail: chironous@uol.com.br), **MARIA PATRÍCIA L. BRITO** (e-mail: mplbrito@yahoo.com.br), and **GILDA V. ANDRADE** (e-mail: gandrade@ufma.br), Departamento de Biologia, Universidade Federal do Maranhão, Campus do Bacanga, Avenida dos Portugueses s/n, 65085-580, São Luís, Maranhão, Brazil.

ANOLIS CRISTATELLUS WILEYAE (Virgin Islands Crested Anole). **SAUROPHAGY.** *Anolis cristatellus* primarily feeds on invertebrates, but has been recorded feeding on fruit (Lazell and Perry 1997. Herpetol. Rev. 28:150), *Sphaerodactylus* geckos (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies. University of Florida Press, Gainesville, 720 pp.) and juvenile conspecifics (GP, unpubl. data). However, predation on lizards is uncommon, and feeding on *Hemidactylus* geckos is unreported. Hence, here we report *A. cristatellus* feeding on *H. mabouia* from the British Virgin Islands.

An adult male *A. cristatellus wileyae* (ca. 70 mm SVL) was observed capturing a juvenile *H. mabouia*, (ca. 25 mm SVL; Fig. 1) at 1000 h on 4 October 2004 on the side of a shed at the H Lavity Stout Community College, Paraquita Bay, Tortola (18°25'24.816N, 64°34'44.287W [datum: WGS84]; elev. < 1 m). When first discovered, the *Hemidactylus* was alive, writhing in the mouth of the *Anolis*. The anole proceeded to struggle with the gecko for the next 4 min, at which point the pair moved out of sight.

This observation expands the reported diet of *A. cristatellus*. *Hemidactylus mabouia* are generally nocturnal, whereas *A. cristatellus* are generally diurnal (but see Perry and Lazell 2000. Herpetol. Rev. 31:247). However, the shed pictured is a nocturnal foraging site for *H. mabouia*, which presumably also use it for shelter during the day, when *A. cristatellus* inhabit the same structure.

Through a Falconwood Foundation grant, The Conservation Agency supported this work. This is manuscript T-9-1037 of the College of Agricultural Sciences and Natural Resources, Texas Tech University.

Submitted by **JENNIFER OWEN** and **GAD PERRY**, Department of Range, Wildlife and Fisheries Management, Texas Tech University, Box 42125, Lubbock, Texas 79409-2125, USA; e-mail: gad.perry@ttu.edu.

BAVAYIA CYCLURA (Forest Bavayia). **PREDATION**. Limited data available on the New Caledonian skink, *Lioscincus nigrofasciolatum*, indicates that it preys on cockroaches, other large insects, and smaller skinks (e.g., *Caledoniscincus* sp.; Bauer and Sadlier 2000. The Herpetofauna of New Caledonia, Society for the Study of Amphibians and Reptiles. 310 pp.). Here, we add to the data on its prey base with an observation of predation on the gecko, *Bavayia cyclura*.

We made the observation at 0900 h on 3 December 2002 during a field study on laticaudine sea snakes conducted during November-December on Îlot Porc-Epic (22°19'S, 166°34'E [datum: IGN 72]; elev. 36 m). We captured an adult specimen (estimated at 90 mm SVL) of *L. nigrofasciolatum* on a tree trunk about 6 m from the shoreline, on the edge of the open forest following the beach. It regurgitated a recently dead adult (49 mm SVL) female *Bavayia cyclura*.

The skink was photographed and released; the gecko (MNHN 2002.0763) was deposited in the herpetological collection of the National Museum of Natural History, Paris, France. Handling of the lizards was done under Permit N° 6034-3588/DRN issued to Ivan Ineich by Direction des Ressources Naturelles de la Province Sud, New Caledonia.

Submitted by **IVAN INEICH**, Muséum National d'Histoire Naturelle, Département de Systématique et Evolution, UMS 602 Taxinomie et Collections (Reptiles), Case courrier n° 30, 25 rue Cuvier, F-75005 Paris, France (e-mail : ineich@mnhn.fr); and **XAVIER BONNET**, CEBC-CNRS UPR 1934, Centre d'Etudes Biologiques de Chizé, F-79360 Villiers en Bois, France.

CARLIA MUNDA (NCN). **PREDATION; FIRE RESPONSE**. Few accounts of predation on Australian lizards exist that identify predator and prey to a species level. Moreover, sparse data exist on the response of most Australian reptiles to fire, despite its widespread occurrence and importance in shaping vegetation associations (see reviews in Gill et al. [eds.] 1981. Fire and the Australian Biota. Australian Academy of Science, Canberra. 582 pp.; Jacobs 1984. *In* Cogger and Cameron [eds.], Arid Australia, pp. 131–142. Australian Museum, Sydney; Bowman 2003. *In* Abbot and Burrows [eds.], Fire in Ecosystems of South-west Western Australia, pp. 108–118. Backhuys Publishers, Leiden). Data are notably poor for species inhabiting Porcupine Grass (*Triodia* spp.) hummock grasslands, a structurally distinctive vegetation unique to Australia (Suijdendorp 1981. *In* Gill et al. [eds.], Fire and the Australian Biota. pp. 417–424. Australian Academy of Science, Canberra; Jacobs, *op. cit.*) that frequently dominates reptile habitats in arid zones on sandy and rocky substrates. Hence, here we document a predation event on the lygosomine skink, *Carlia munda*, and its apparent relationship to fire in a *Triodia*-dominated vegetation near the northwest edge of the Great Sandy Desert in Western Australia.

At 1930 h (night) on 21 December 1985, MP observed a freshly road-killed mature Brown Falcon, *Falco berigora berigora*, in close association with two dead but intact *C. munda* on the NW coastal Hwy 6.7 km S of Cane River Crossing (22°04'S, 115°34'E [datum: AUS84]; elev. 30 m). One *Carlia* had only its tail protruding from the falcon's beak; the other was on the road 10 cm from the head of the dead bird; both lizards exhibited no evidence of external injury. A fire, visible from 2–3 km away, was still slowly burning in a northeasterly direction through the scrub and grassland within 10 m of the west side of the road; the burnt area next to the road extended for hundreds of meters. The habitat consisted of *Triodia* hummocks with scattered *Acacia* bushes on a stony plain with low stony ridges. Three additional lizard species were found on the road during a thorough search of the ~100 m along which the fire front moved over the next hour. These comprised: 1 adult *Delma nasuta* (Pygopodidae); 4 adult *Cyclodomorphus melanops melanops* (Scincidae: Lygosominae), of which 1 female later gave birth to 2 live young; and 1 adult *Heteronotia binoeii* (Gekkonidae). These animals were moving from the burning side towards the opposite side of the road; as no other reptiles were seen on the road on either side of the fire-affected stretch, all were probably fleeing the fire. Additionally, one adult *Lophognathus longirostris* (Agamidae) was found active on the ground among the blackened *Acacia* stems remaining next the road. Except for the two *Carlia*, all animals were uninjured.

The falcon probably obtained the *C. munda* from foraging at the margins of the fire. This and other smaller raptor species such as Black Kites, *Milvus migrans*, are well-known attendants of fires by day in the Australian arid zone (e.g., Olsen et al. 1993. Birds of Prey and Ground Birds. The National Photographic Index of Australian Wildlife/Angus and Robertson, Sydney. 200 pp.), occasionally in aggregations of hundreds (pers. obs.), and fire-margin foraging by opportunistic predators is documented in other ecosystems (e.g., Secretary Birds, *Sagittarius serpentarius*, in African veld; Steyn 1982. Birds of Prey of southern Africa. David Philip, Cape Town). Similarity in the condition of both *C. munda* implies that both were prey. This record also implies nocturnal foraging by the typically diurnal *F. b. berigora* might occur where fire provides 'artificial' light; Olsen et al. (*op. cit.*) also report flying and calling at night. Both *D. nasuta* and *C. melanops melanops* are intimately associated with *Triodia*, so our observations suggest that at least some individuals flee burning habitat; whether these individuals would use loose soil or burrow refuges, when available, is unknown. As fires in hummock grassland might be extensive, sometimes lasting for months and passing over hundreds of square kilometers (Suijdendorp, *op. cit.*; pers. obs.), raptor performance as lizard predators on advancing fire lines in such habitats and its effect on post-fire lizard populations might have special interest.

The two *C. munda* were deposited as vouchers in the collection of the Western Australian Museum (R94385-6); the bird was discarded. Brenda Coulson assisted in the field. Marc Hayes critically reviewed the manuscript.

Submitted by **DEAN C. METCALFE**, PO Box 4056, Werrington, New South Wales, Australia 2747 (e-mail: dean_metcalfe@yahoo.com.au); and **MAGNUS PETERSON**, Unit 5/33 Point Walter Rd., Bicton, Western Australia, Australia 6157 (e-mail: lizardman1955@yahoo.com.au).

CHAMAELEO GRACILIS (Graceful Chameleon). **REPRODUCTION IN FLORIDA.** Florida and Hawaii are the two states in the United States with the most severe invasive species problems (U.S. Congress 1993. Harmful Non-indigenous Species in the United States. Office of Technology Assessment, OTA-F-565,

Government Printing Office, Washington, D.C. 155 pp.). Over the last 50 years, increasing numbers of exotic lizard populations have been documented as established in Florida, with the number of non-native species breeding in the state now exceeding the number of native species (Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida, Krieger Publishing Company, Malabar, Florida. 155 pp.). Among the many exotic lizard species known to have breeding populations in Florida, only one true chameleon, *Chamaeleo calyptratus*, is recorded as established (http://wld.fwc.state.fl.us/critters/exotics). Hence, we provide here an observation that may indicate that *Chamaeleo gracilis* also is reproducing in Florida.

At ca. 0930 h on 10 December 2004, an adult female *C. gracilis* (ca. 120 mm SVL) was captured walking on the center line of Citrus Blvd. in Palm City (27°02.507'N, 80°22.701'W, [datum: NAD27]; elev. 3 m). This represents the 2nd capture of a *C. gracilis* in this area, and several other sightings have been documented (Harold Parker, pers. comm.). The lizard seemed dehydrated and physically distressed, and was clearly gravid. After treatment by a veterinarian, it laid 22 eggs, about half of which seemed viable. After oviposition, the chameleon remained enlarged with additional eggs, but died before it could lay the remaining eggs. The overall number of eggs (~45) this specimen contained was towards the upper range recorded for the species (Spawls et al. 2002. A Field Guide to the Reptiles of East Africa. Academic Press, London. 543 pp.).

Multiple sightings of *C. gracilis* in the same area that includes a gravid female with viable eggs suggests that natural reproduction of this species might be occurring in Palm City, Florida.

ENGEMAN**, National Wildlife Research Center, 4101 LaPorte Ave., Fort Collins, Colorado 80521-2154, USA (e-mail: Richard.m.engeman@aphis.usda.gov); **DESTA HANSEN**, Hobe Sound Nature Center, P.O. Box 214, Hobe Florida 33455, USA; and **HENRY T. SMITH**, Florida Department of Environmental Protection, Florida Park Service, 13798 S.E. Federal Highway, Hobe Sound, Florida 33455, USA.

EGERNIA FORMOSA (Goldfields Crevice-skink). **ENDOPARASITES.** *Egernia formosa* is a medium-sized (adults 80 mm SVL) skink known from the interior of Western Australia (Cogger 1996. Reptile & Amphibians of Australia, 6th ed., Ralph Curtis Publ., Sanibel Island, Florida. 808 pp.). To our knowledge, no previous reports of parasites exist for *E. formosa.* The purpose of this note is to report the cestode *Oochoristica piankai* and the nematode *Pharyngodon hindlei* from *E. formosa.*

We examined 4 *E. formosa* (LACM 56427, 56431–56433; mean SVL = 92 mm ± 8.4 SD, range: 83–101 mm) collected January 1968, 70 km SW Wiluna, Western Australia, (27°05'S, 119°37'E, [datum: AGD66]; elev. 503 m) in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California. The stomachs had previously been removed; the small and large intestines and body cavity were examined for helminths. Found in the small intestine of one skink (LACM 56432) were 15 *O. piankai* (prevalence: number infected/number examined x 100 = 25%). All 4 skinks contained *P. hindlei* in the large intestines (prevalence = 100%), mean intensity (mean number helminths per infected lizard) = 62.8 ± 25.9 SD, range: 26–82. Parasites were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland as *Oochoristica piankai* (USNPC 96231) and *Pharyngodon hindlei* (USNPC 96232).

Bursey et al. (1996. J. Helminthol. Soc. Washington 63:215–221) described *Oochoristica piankai* from *Moloch horridus*. Cestodes require two hosts (intermediate and definitive) for completion of their life cycle (Roberts and Janovy 2005. Gerald D. Schmidt & Larry S. Roberts' Foundations of Parasitology, 7th ed., McGraw Hill Higher Education, Boston 702 pp.). The intermediate host of *O. piankai* is unknown; however, Hickman (1963. Pap. Proc. Royal. Soc. Tasmania 97:81–104) reported a tenebrionid beetle served as the intermediate host of *Oochoristica vacuolata. Oochoristica piankai* has previously been reported from *Ctenophorus fordi, C. isolepis, C. reticulatus,* and *Nephrurus laevissimus* (Bursey and Goldberg 1999. Comp. Parasitol. 66:175–179; Goldberg et al. 2000. Comp. Parasitol. 67:108–114). Baylis (1930. Ann. Mag. Nat. Hist. 10:354–366) previously reported *Pharyngodon hindlei* in the skink *Tiliqua scincoides. Pharyngodon hindlei* is a member of the Oxyuroidea all of which have direct life cycles that do not involve an intermediate host (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission, 2nd ed., CABI Publishing, Oxford, United Kingdom. 650 pp.). Infection likely occurs by exposure to substrate that has been contaminated with feces containing eggs. *Egernia formosa* is the second host recorded for this nematode. *Egernia formosa* represents a new host record for both *O. piankai* and *P. hindlei.*

We thank Christine Thacker (LACM) for permission to examine *E. formosa* and Dustin Goto (Whittier College) for assistance with dissections.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb@psu.edu).

EGERNIA STRIATA (Elliptical-eye Skink). **ENDOPARASITES.** *Egernia striata* is a medium-sized (100 mm SVL adults) skink widely distributed through the interior of western to southwestern Northern Territory and northwestern South Australia (Cogger 1996. Reptiles & Amphibians of Australia, 6th ed., Ralph Curtis Publ., Sanibel Island, Florida, 808 pp.). To our knowledge, the only parasites previously reported from *E. striata* are the nematodes: *Parapharyngodon kartana, Pharyngodon tiliquae, Wanaristrongylus ctenoti* (Goldberg and Bursey 2000. Trans. Royal Soc. S. Aust. 124:127–133), *Johnpearsonia egerniae* (Durette-Desset et al 1994. Parasite 1:153–160), *Physalopteroides filicauda, Skrjabinoptera goldmanae,* and *Wanaristrongylus papangawurpae* (Jones 1995. Aust. J. Zool. 40:115–126). The purpose of this note is to report the pentastome *Kiricephalus* from *E. striata.*

One pentastome nymph was found in the body cavity of one female *E. striata* (95 mm SVL) from the herpetology collection of the Natural History Museum of Los Angeles County (LACM) collected 4 January 1968, 34 km W. Lorna Glen Homestead (26°14'S, 121°13'E, [datum: AGD66]; elev. 500 m), Western Australia; the *E. striata* was catalogued as LACM 56562. The

pentastome nymph was cleared in cederwood oil and identified as *Kiricephalus* sp.; it was deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland as USNPC 95509.

Nymphs of *Kiricephalus* sp. have been reported from anurans and snakes, but only two species of lizards: *Hemidactylus frenatus*, *Japalura swinhonis* (Bursey and Goldberg 2004. J. Parasitol. 90:1428–1433). Intermediate hosts include insects. After ingestion by a lizard, *Kiricephalus* larvae hatch, whereupon they metamorphose into nymphs that are infective to a final host that preys on the lizard (Roberts and Janovy 2005. Gerald D. Schmidt & Larry S. Roberts' Foundations of Parasitology, 7th ed., McGraw Hill Higher Education, Boston, 702 pp). *E. striata* is a new host record and Australia is a new locality record for *Kiricephalus* sp. We thank Christine Thacker (LACM) for permission to examine *E. striata*.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); and **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb@psu.edu).

FURCIFER OUSTALETI, FURCIFER RHINOCERATUS (NCN). **DENSITY.** Habitat destruction and collection pressure due to herpetocultural popularity threatens many Malagasy chameleons (Jenkins et al. 1999. Oryx 33:37–45). Fieldwork has focused on needed species inventories, but sparse attention has been devoted to estimating population densities, data required to reliably estimate the effects of habitat destruction and direct exploitation on chameleon populations (Jenkins et al., *op. cit.*). In particular, data on the genus *Furcifer* are notably sparse. Hence, we provide density data on *Furcifer oustaleti* and *F. rhinoceratus* from western Madagascar.

Our estimates of density and relative abundance were obtained in a dry deciduous forest habitat during a six-week survey (July-August 1997) on chameleons in Ampijoroa (46°19'E, 16°23'S [datum: WGS72]; elev. ~300 m). A total of 8 km was surveyed that comprised 288 different 30-m transects in two different forest subtypes: low canopy (*lc*) and high canopy (*hc*). We distinguished these categories visually, respectively, as corresponding to a canopy < 12 m versus ≥ 12 m. Transects were run using headlamps starting at dusk until all transects were surveyed; this usually spanned the period 1900–2300 h. Twelve different transects were surveyed each night for 24 nights. Relative abundances were estimated as the total number of individuals of each species seen divided by distance covered. We tested for differences in relative abundance between the forest subtypes using a Mann-Whitney test; each sample night was a data point. Absolute densities were estimated using distance sampling (Buckland et al. 1993. Distance Sampling: Estimating the Abundance of Ecological Populations. Chapman and Hall, London. 446 pp.).

A total of 111 individuals were located. Forty of 53 *F. rhinoceratus* were in high canopy forest; similarly, 50 of 58 *F. oustaleti* were in the same forest subtype. We found no significant difference in species composition between forest subtypes ($\chi^2 = 5.99$, $P = 0.23$), so the species were grouped for further analysis. Relative abundance in high canopy habitat (mean = 1.6 individuals/100 m, $N_{hc} = 17$) was significantly higher than in low canopy habitat (mean = 0.8 individuals/100 m, $N_{lc} = 8$; $P < 0.05$). Densities (confidence intervals in parens) ranged from an average of 5.8 (3.3–10.2) individuals/ha in the low canopy subtype to 13.9 (7.4–26.2) individuals/ha in the high canopy subtype.

Our density estimates are considerably lower than estimates for similar rainforest species obtained using similar methods (~33 individuals/ha; Jenkins et al., *op. cit.*). The ecological basis of underlying differences between the canopy subtypes we examined, and between rainforest and deciduous dry forest habitats are not known, but may be related to abundance of chameleon prey items which are likely to be sensitive to microhabitat conditions.

FURCIFER OUSTALETI, FURCIFER RHINOCERATUS (NCN). **PREDATION.** About half of all known chameleon species are from Madagascar (Glaw and Vences. 1994. 2nd Edition. Zoologisches Forshunginstitut und Museum Alexander Koenig, Bonn. 480 pp.), and many of these are threatened by habitat destruction (Raxworthy et al. 2003. Nature 426:837–841). Details of their spatial distribution are increasingly well described (Raxworthy et al., *op. cit.*), but almost nothing is known about their role in Malagasy food webs. Hence, we report observations of predation events on two species of *Furcifer* by three different predators, and indirect evidence of predation by a fourth predator. We made all observations in a dry deciduous forest habitat during a six-week survey (July–August 1997) in Ampijoroa (46°19'E, 16°23'S [datum: WGS72]; elev. ~300 m).

On 2 July 1997, we encountered an adult Big-eyed Snake, *Mimophis mahafalensis* (ca. 80 cm total length) along a forest path entwined around an adult male *Furcifer rhinoceratus* (~180 mm total length). Although the chameleon was still alive, it had lost its colouration and was almost completely white. The chameleon ceased struggling ca. 5 min after the initial detection, whereupon the snake began to ingest it headfirst. Complete ingestion of the chameleon was quite rapid and took a little less than 10 min. *M. mahafalensis* is a common, mostly terrestrial opisthoglyphous colubrid common in dry habitats (Glaw and Vences, *op. cit.*; Henkel and Schmidt 2000. Amphibians and Reptiles of Madagascar and the Mascarene, Seychelles, and Comoro Islands, Krieger Publishing Co., Malabar, Florida. 316 pp.), so it may have encountered the chameleon while the latter was crossing the forest path.

On 9 July, soon after its release, we observed a juvenile female

F. rhinoceratus (~80 mm total length) captured by a previously unobserved large adult male *F. oustaleti* (~600 mm total length). The larger chameleon was on a bush about 0.5 m high, and extended its tongue over at least 0.3 m to make the capture. The smaller chameleon's skull was crushed instantly between the predator's jaws. *F. oustaleti* is the largest of all known chameleon species (Glaw and Vences, *op. cit.*; Henkel and Schmidt, *op. cit.*), and this observation substantiates other reports that small vertebrates, as well as the more typical insect fare, are dietary components for this species.

On 12 July 1997, an adult Crested Coua, *Coua cristata,* was observed capturing a female adult *F. oustaleti* (~300 mm total length). The interaction had begun prior to our encountering the chameleon. The chameleon clung to a slender stem ca. 0.5 m off the ground. The *C. cristata* pecked at the chameleon four times, at roughly one minute intervals, hopping backwards between pecks. The chameleon rose in a defensive position to meet each peck with its two forelegs outstretched and its mouth wide open, its tail wrapped around the stem for balance. After being pecked the fourth time, it fell to the ground; the *C. cristata* picked it up in its beak and ran off into the undergrowth. Crested Couas are known to feed by carefully searching dense foliage and inspecting branches (Langrand 1990. Guide to the Birds of Madagascar. Yale University Press, New Haven, Connecticut. 364 pp.); such detailed investigative behavior might explain how it detected the cryptic chameleon.

During July 1997, we found > 17 skulls of *F. oustaleti* beneath the nest of a buzzard, *Buteo brachypterus,* in a large tree. The skulls were clean, not in regurged pellets. *Buteo brachypterus* often sit on observation posts in forests (Langrand, *op. cit.*). This may reflect survey behavior that could contribute to this raptor's apparent success as a chameleon predator despite their crypsis.

We thank Département des Eaux et Forêts, and the Association National pour la Gestion des Aires Protégés for permission to do this work, and the Royal Geographical Society for funding. We also thank Marc Hayes for suggestions to the manuscript.

Submitted by **JESSICA METCALF**, Max Planck Institute for Demographic Research, Konrad-Zuse-Straße 1, 18057 Rostock, Germany (e-mail: jessicametcalf@hotmail.com); **NICK BAYLY**, The Wetland Trust, Elm's Farm, Pett Lane, Icklesham, East Sussex, TN36 4AH UK; **MICHEL BISOA**, Dept de Biologie Animale, Faculté des Sciences, BP 906, Antananarivo 101, Madagascar; **JEANNENEY RABEARIVONY**, Dept de Biologie Animale, Faculté des Sciences, BP 906, Antananarivo 101, Madagascar; **ALEX STEWART-JONES**, Ecology and Evolutionary Biology, School of Biological Sciences, Bassett Crescent East, Southampton SO16 7PX, UK.

GAMBELIA WISLIZENII **(Leopard Lizard). OPHIOPHAGY.** Predation on vertebrates is well known in leopard lizards (*Gambelia*). Other lizards comprise most vertebrate prey (Pack 1922. Proc. Biol. Soc. Washington 35:1–4, Knowlton and Thomas 1936. Copeia 1936:64–66, McCoy 1967. Amer. Midl. Nat. 77:138–146, Tanner and Krogh 1974. Herpetologica 30:63–72, Pianka and Parker 1976. Herpetologica 32:95–114), but small mammals are also occasionally eaten (Pietruszka et al. 1981. J. Herpetol. 15:249–250). Notably, unlike the closely related *Crotaphtyus collaris*, which are known to eat snakes (Best and Pfaffenberg 1987. Southwest Nat. 32:415–426; Baird 2000. Herpetol. Rev. 31:104), *Gambelia wislizenii* is not recorded as being ophiophagous. Here, we document an instance of *G. wislizenii* having taken a Western Shovel-nosed Snake, *Chionactis occipitalis*.

At ca. 1000 h on the 29 May 2003, we captured an adult male *G. wislizenii* on the Barry M. Goldwater Range (BMGR), Yuma Co., Arizona (32º27'38.5"N, 114º28'48.9"W [datum: WGS84]; elev. 116 m). The animal was first spotted fleeing from under a creosote bush (*Larrea tridentata*) in a dune area before eventually disappearing into a hole ca. 80 m away. We retrieved the exhausted animal from the hole and noticed its stomach was greatly distended. Opening the mouth revealed the tail of a snake protruding from

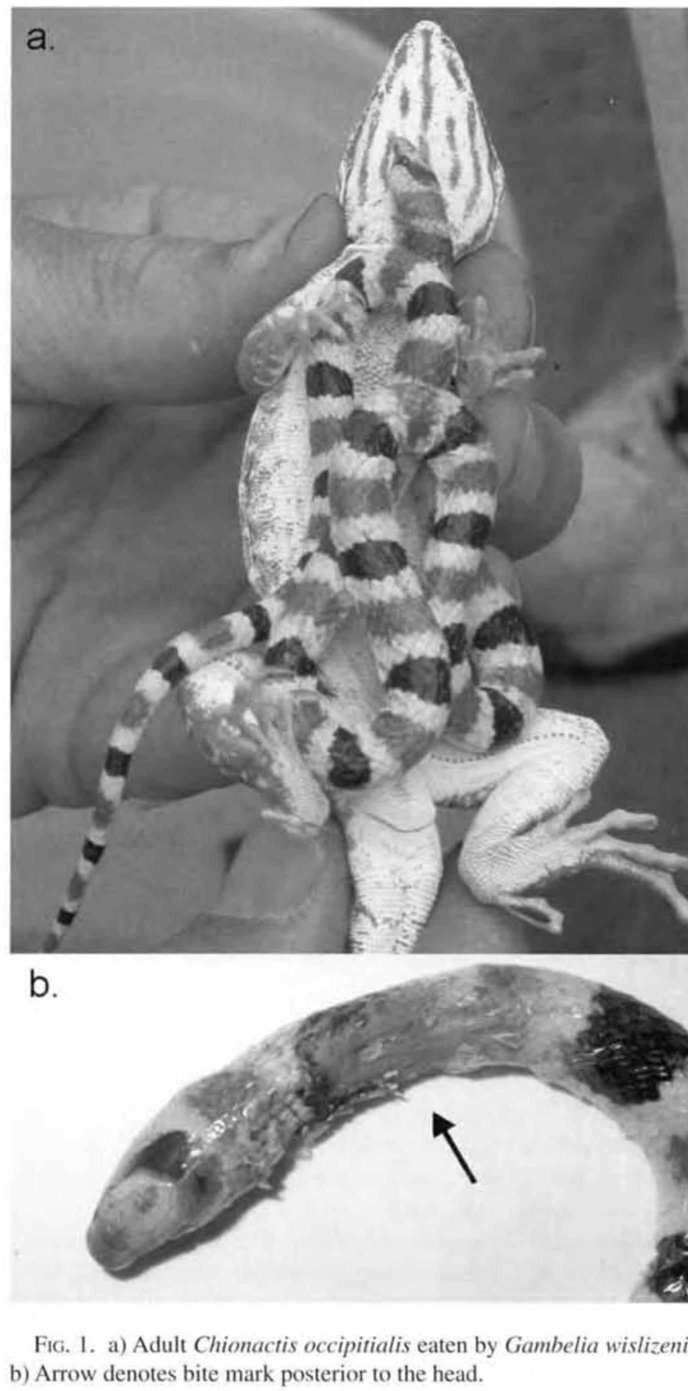

Fig. 1. a) Adult *Chionactis occipitialis* eaten by *Gambelia wislizenii.* b) Arrow denotes bite mark posterior to the head.

the esophagus; removal of the snake revealed that the *G. wislizenii* (103.5 mm SVL, 33.5 g) had eaten a *C. occipitalis* (340.3 mm total length, 7.8 g). Thus, the prey was over 3 times the length and weighed 23% of the body mass of the *G. wislizenii* (Fig. 1a). We found four bite points on the *Chionactis*, all within the first 18 cm of the head. The most substantial of these bites was 5 mm behind the head (Fig. 1b), having torn the skin away, leaving the underlying musculature exposed.

Although *Crotaphytus* is known to immobilize prey by crushing the head, the "torso compression" behavior evidenced here is consistent with that of *Gambelia* feeding on other vertebrates (Lappin 1999. Ph.D. Dissertation, Univ. California, Berkeley; Pietruszka et al. 1981. J. Herpetol. 15:249–250). The predominately fossorial and crepuscular/nocturnal activity of *C. occipitalis* (Brattstrom 1952. Herpetologica 8:61–63) would appear to make it an unlikely prey item for *G. wislizenii*. However, rather extensive diurnal activity has been reported for *C. occipitalis* in this region (Rorabaugh 2002. Sonoran Herpetol. 15:32–33), suggesting it may be more common in the diet of diurnal predators then we would predict from this initial observation.

We thank the Natural Resource Division of the Marine Corps Air Station in Yuma, Arizona for access to the BMGR range and Bryan Morrill for help in the field.

Submitted by **JAY J. MEYERS,** Northern Arizona University, Flagstaff, Arizona 86011, USA (e-mail: jjm@dana.ucc.nau.edu); and **ANTHONY HERREL** and **BIEKE VANHOOYDONCK,** University of Antwerp, B-2610 Antwerp Belgium.

GAMBELIA WISLIZENII (Long-nosed Leopard Lizard). **ARBOREAL BEHAVIOR**. In the North American southwest, leopard lizards (genus *Gambelia*) are characteristically ground dwelling (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, 3rd ed., Houghton-Mifflin, New York. 533 pp.; Smith 1946. Handbook of Lizards, Comstock Publishing Co., Ithaca, New York. 557 pp.). In *G. wislizenii,* climbing is not mentioned in several substantive ecological studies of this species (Parker and Pianka 1976. Herpetologica 32:95–114; Tanner and Krogh 1974. Herpetologica 30:63–72), and to our knowledge, only a few records exist of climbing in this species. Clark (1974. Trans. Kansas Acad. Sci. 77:68) observed a *G. wislizenii* perched 30 cm off the ground in a shrub, and Miller and Stebbins (1964. The Lives of Desert Animals in Joshua Tree National Monument. University of California Press, Berkeley. 452 pp.) mentioned collecting an individual on top of a "massive rock 30 feet from the ground." Crowley and Pietruszka (1983. Anim. Behav. 31:1055–1060) commented that this species often climbs into shrubs or onto rocks, but did not provide additional information. For this reason, we augment the limited data on climbing in *G. wislizenii* with an observation from the Mojave Desert of California (USA).

At 0930 h (PST) on 13 September 2003, we observed a juvenile (70 mm SVL, 7.6 g, sex undetermined) *G. wislizenii* perched on the vertical stump of a dead Joshua Tree (*Yucca brevifolia*). The site, 9 km NW of Piñon Hills, Los Angeles County (117°42'W, 34°29'N [datum: WGS84]; elev. 1070 m), is on the edge of the Mojave Desert in Joshua tree woodland and creosote scrub habitat. The lizard was perched 117 cm above the ground in full sunlight and oriented 15–20° from vertical on the 134-cm high stump. Air temperature at time of capture was estimated at 32.0°C (data from Saddleback Butte 22 km to the NW).

Arboreality in other desert lizards is sometimes attributed to thermoregulatory behavior (e.g., Adolph 1990. Ecology 71:315–327), but climbing is probably not an important part of the thermoregulatory repertoire of *G. wislizenii* because this behavior seems infrequent (but see Crowley and Pietruszka, *op. cit.*, for an alternative view). Detailed accounts of thermoregulatory behavior in *G. wislizenii* are lacking, although McCoy (1967. Amer. Midl. Nat. 77:138–146) describes diel activity consistent with the thermoregulatory pattern well known for many desert lizards, seeking shade during the hotter parts of the day and basking in the sun either on the ground or on rocks in the morning and late afternoon. *Gambelia wislizenii* may use arboreal perches to survey for and ambush Side-blotched Lizards (*Uta stansburiana*), a common prey item that is abundant at this site and sometimes is observed to climb Joshua Trees (SCA, pers. obs.).

Submitted by **SEAN FOGARTY** and **STEPHEN C. ADOLPH**, Department of Biology and Center for Environmental Studies, Harvey Mudd College, 301 E. Twelfth St., Claremont, California 91711, USA; e-mail: adolph@hmc.edu.

GERRHONOTUS PARVUS (Pygmy Alligator Lizard). **MAXIMUM SIZE**. *Gerrhonotus parvus*, an anguid endemic to Nuevo León, Mexico, is known from only three specimens 55.0–71.7 mm SVL in size (Knight and Scudday 1985. Southwest. Nat. 30: 89–94; Banda-Leal et al. 2002. Southwest. Nat. 47:614–615). The largest, an adult female (71.7 mm SVL), was maintained in captivity for five years before being described as the paratype (Knight and Scudday, *op. cit.*). Here, we report on additional individuals of *G. parvus* that increase the known maximum size.

Since the collection of the third known specimen in May 2001 (Banda-Leal et al., *op. cit.*), we have found four additional *G. parvus*. These lizards, all adult males, ranged in size from 65.8 to 76.5 mm SVL. All were found in arid transition woodland characterized by oak (*Quercus* sp.), agaves (*Agave* spp.), sotol (*Dasylirion* sp.), and extensive outcrops of limestone at elevations of 1600–1650 m. The largest of the four, found dead in a canyon bottom near San Isidro, Municipio Santiago, Nuevo León, on 11 October 2004, represents the largest known *E. parva*. It had an unbroken tail 130.0 mm long, and a mass of 8.1 g.

The largest *G. parvus* (UANL 6675) was deposited in the Universidad Autónoma de Nuevo León herpetological collection. Research and collecting were conducted under the authority of SEMARNAT scientific research permits OFICIO NÚM/SGPA/DGVS/01612 and 01454 issued to DL.

GONOCEPHALUS ABBOTTI (Abbott's Anglehead Lizard). **ENDOPARASITES.** *Gonocephalus abbotti* is known from Malaysia and southern Thailand (Denzer and Manthey 1991. Raffles Bull. Zool. 39:309–322). We know of no reports of endoparasites from this species. The purpose of this note is to report two species of nematodes from *G. abbotti*.

One male *G. abbotti* (175 mm SVL) was collected 11 August 2004 in the Temengor Forest Reserve, Perak State, (05°24'–34'N, 101°33'–39'E [datum: AGD84]; elev. 750 m), West Malaysia. It was deposited in the La Sierra University Herpetological Collection as LSUHC 7035. Two species of nematodes were present in the body cavity and preserved in 10% formalin. The nematodes were cleared in a drop of concentrated glycerol and identified as *Orneoascaris sandoshami* (1 female, 1 male) and *Gonofilaria rudnicki* (2 females, 4 males). The nematodes were deposited in the United States National Parasite Collection, Beltsville, Maryland as: *Orneoascaris sandoshami* (USNPC 95687) and *Gonofilaria rudnicki* (USNPC 95688).

Orneoascaris sandoshami is known only from a captive *Megophrys montana* (Sprent 1985. Ann. Parasit. Hum. Comp. 60:33-55). *Gonofilaria rudnicki* has previously been found in *Gonocephalus borneensis*, *Acanthosaura armata* and *Limnonectes macrodon* from Malaysia (Mullin 1973. Proc. Helm. Soc. Wash. 40:282-285). *Gonocephalus abbotti* represents a new host record for both *O. sandoshami* and *G. rudnicki*.

The *G. abbotti* was collected under authority of permit 40/200/19SJ.1105 issued to LLG by the Environmental Planning Unit of West Malaysia.

HELODERMA HORRIDUM HORRIDUM (Mexican Beaded Lizard). **UNUSUAL HABITAT**. *Heloderma horridum horridum* is a tropical lizard distributed along the Pacific coastal areas of México (Sonora, Sinaloa, Jalisco, Morelos, Guerrero, Oaxaca, Chiapas) and lowland Guatemala (Bogert and Martin Del Campo, 1956. Bull. Amer. Mus. Nat. Hist. 109:1–238). Here, we report an observation of *H. h. horridum* from a habitat atypical for the species at an elevation higher than all previous records.

At ca. 1800 h on 11 June 2004, OMV encountered an adult (730 mm SVL) *H. h. horridum* walking across a dirt road of 4 m wide in the Reseva Estatal Sierra de Nanchititla, Estado de México, México (18°51'31.4"N, 100°25'34.7"W, datum: NAD27; elev. 1861 m). The habitat consisted of a mixed *Quercus elliptica* and *Pinus oocarpa* forest.

This vegetation association is atypical for this venomous lizard, which is typically found in tropical deciduous forest and thorn scrub forest (Bogert and Martin Del Campo, *op. cit.*). Moreover, the record is 332 m higher than the highest elevation at which *H. h. horridum* has been previously recorded and expands their known distribution 20 km south (Aguilar-Miguel et al. 2003. Herpetol. Rev. 34:384).

A color photographic voucher (CNAR-IBH RF 024) of the *H. h. horridum* was deposited in the herpetological collection of Instituto de Biología, Universidad Nacional Autónoma de México.

Submitted by **OCTAVIO MONROY-VILCHIS**, **OSWALDO HERNÁNDEZ-GALLEGOS**, and **FELIPE RODRÍGUEZ-ROMERO**, Facultad de Ciencias, Centro de Investigación en Recursos Bióticos–CIRB, Universidad Autónoma del Estado de México, Instituto Literario # 100, 50000, Toluca, Estado de México, México (e-mail: omv@uaemex.mx).

LAMPROPHOLIS DELICATA (Delicate Skink, Rainbow Skink). **INTRODUCTION.** Lord Howe Island, a 1455-ha island ca. 700 km NE of Sydney off the New South Wales coast (31°30'–31°36' S; 159°00'–159°17' E), was listed as a World Heritage Site in 1982 because of its high conservation value (Hutton 1986. Lord Howe Island. Conservation Press, Canberra, Australia. 157 pp.). It has unique biota and landforms, with a very high degree of endemism, including two endemic lizards (Hutton, *op. cit.*). Introduced taxa, which include the Ship Rat, *Rattus rattus*, a problem for the endemic lizards, have been documented on Lord Howe Island (Cogger 1971. Proc. Linn. Soc. New South Wales 96:23–38), but no documentation of introduced lizards existed. Hence, we report the extensive establishment of the eastern Australian skink, *Lampropholis delicata* on Lord Howe Island.

Over the interval 28–30 November 1998, the we undertook a lizard survey of Lord Howe Island in part to determine the validity of recent reports about the presence of *L. delicata*. We observed, captured and identified lizards wherever we saw them in all major habitats on the island. The island, ca. 11 km long and 2.8 km wide at its widest point, is roughly dumbbell-shaped, with two volcanic mountains (Lidgbird and Gower) dominating the south end, and low hills of basaltic origin in the north. Alluvial lowlands occur between these regions, and provide the area of human habitation and most of the adjacent farmland. The habitats that we visited were cultivated urban gardens and associated uncultivated urban vegetation, coastal grassland, beaches, low shrubland on the northern end of the island and closed palm and broad-leaf forest on the south end of the island. We only surveyed half way up the 777-m Mt Lidgbird, and did not visit 875-m Mt Gower. We found *L. delicata* in both urban/semi-urban (Middle Beach Road, adjacent to the Aquatic Club, in front of "Pinetrees" resort) and undisturbed areas (Catalina crash site, track up Malabar Hill) in the hills to the north of the township of Lord Howe Island. Nests of eggs were also located under clumps of soil in the cultivated urban gardens at Pinetrees resort. We did not locate *L. delicata* at the southern mountainous end of the island. On the urban and northern end of Lord Howe Island, *L. delicata* was abundant (10s to 100s per hectare).

Precisely how long *L. delicata* has been established on Lord Howe Island is unknown, but an earlier extensive survey (Cogger, *op. cit.*) did not record it. Thus, *L. delicata* probably has been present on Lord Howe Island for < 30 years. As *L. delicata* has been introduced (presumably in cargo) to both New Zealand (Gill and Whitaker 1996. New Zealand Frogs and Reptiles. Bateman Field Guides, David Bateman Ltd., Auckland, New Zealand. 112 pp.) and the Hawaiian Islands (Baker 1979. Pacific Sci. 33:207–

212), and as its distribution on Lord Howe Island is centered on human-altered areas, it probably also travelled to Lord Howe Island with cargo. *Lampropholis delicata* has the potential to impact the endemic Lord Howe Island skink, "*Cyclodina*" *lichenigerum*, a species that has greatly declined in the face of human occupation of the island (Cogger, *op. cit.*). *Lampropholis delicata* is thought to be out-competing *Lipinia noctua*, and possibly *Emoia cyanura*, in Hawaii (Baker, *op. cit.*), although these species are smaller than *C. lichenigerum*. Elements of the endemic invertebrate fauna on Lord Howe Island (still largely undocumented) might also be at risk; *L. delicata* eats a wide range of invertebrates in Hawaii. On the Hawaiian Islands, *L. delicata* occurs in both open and vegetated habitats, as well as urban areas, and also at high altitude (Baker, *op. cit.*). Hence, we predict that *L. delicata* will eventually inhabit the whole of Lord Howe Island, including Mt Gower and Mt Lidgbird, which are not as high as *L. delicata* occurs in Hawaii (1220 m) (Baker, *op. cit.*). The invasive nature of *L. delicata* means that care should be taken to prevent its spread to adjacent islands.

We collected five vouchers and tissue samples (South Australian Museum R51734-38, plus two neonates hatched from eggs, R52444-45) for future genetic analysis to identify the source of the founder population. This work was conducted under Scientific Investigation License 2434 from the NSW National Parks and Wildlife Service and University of Sydney Animal Care and Ethic Approval L04/9-98/1/2829.

LEIOCEPHALUS CARINATUS ARMOURI (Northern Curly-tailed Lizard). **CANNIBALISM**. Florida is one of two states in the United States with the most severe invasive species problems (U.S. Congress, 1993. Harmful Non-indigenous Species in the United States. Office of Technology Assessment, OTA-F-565, Government Printing Office, Washington, D.C.). *Leiocephalus carinatus armouri*, one of many species of introduced lizard in Florida, has been rapidly expanding its range (Smith et al., *in press*, International Biodeterioration and Biodegradation; Smith and Engeman 2003. Florida Park Service Technical Report, Hobe Sound, Florida). The few dietary studies on *L. carinatus* indicate that prey is almost entirely comprised of insects (Callahan 1982. Geographical and ecological distribution of the lizard *Leiocephalus carinatus armouri* in South Florida. MA Thesis, University of South Florida, Tampa, Florida.). Meshaka et al. (2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publishing Company, Malabar, Florida. 166 pp.) likewise reported 60 lizards collected from Palm Beach County consumed mostly beetles, roaches, and ants, with 11 other invertebrate taxa also represented. However, Callahan (*op. cit.*) observed Northern Curly-tailed Lizards capture two exotic *Anolis sagrei*, and Schoener et al. (2002. Ecol. Monogr. 72:383–407) showed that experimental introductions of *L. carinatus* to small tropical islands had immediate major negative effects on *A. sagrei* population density. Here we add to range of observations of saurophagy in *L. c. armouri* with an observation of cannibalism from Florida, USA.

On 6 Feb 2004, a mostly sunny day (24–25°C air temperature), CLD observed a basking adult *L. c. armouri* with a smaller lizard in its mouth in the parking lot of Tequesta Shoppes (105-191 US Hwy 1) in Tequesta (25°67.669'N, 080°05.059'W [datum: WGS84]; elev. 5 m). Upon collection of the 93 mm SVL lizard, its prey (already dead when captured) was found to be another *L. c. armouri* 55 mm SVL. Despite the observations of predation on *A. sagrei*, this is the first evidence of cannibalism in *L. carinatus*, a phenomenon that could produce ontogenetic shifts in habitat use.

LIOLAEMUS PETROPHILUS (NCN). **PREDATION**. Birds are often reported to feed on lizards (e.g., Terres 1991. The Audubon Society Encyclopedia of North American Birds. Wing Books, New York, New York. 1109 pp.; Trejo et al. 2003. Herpetol. Rev. 34:145), but field observations of such predation are infrequent. Hence, we report an observation of a Black-bellied Shrike-tyrant (*Agriornis montana*) preying on a *Liolaemus petrophilus* from southern Argentina.

Our observation was made during a herpetological and ornithological survey of the Somuncura Plateau, Valcheta Department, Rio Negro Province (41°07'41.4"S, 66°49'21.3"W [WGS 84], elev. 800 m) using 8 x 30 binoculars from a distance of ca. 15 m. At ca. 1600 h on 4 January 2002, CHFP observed an adult male Black-bellied Shrike-tyrant attack a subadult (ca. 120 mm total length) *L. petrophilus*. The lizard had been basking for 10 min on a large boulder at the edge of a small rocky canyon when the bird was first observed perched on the top of a small shrub at least 8 m from the lizard. After 2–3 min, the bird attacked and seized the lizard with his bill across the neck and upper thorax. After the bird secured the lizard, it flew to a rock 1–2 m away, where it pecked at the lizard and beat it against the rock. After the lizard appeared immobile, the bird laid the lizard on the rock, observed it for a few seconds before giving it several more pecks, then it seized the lizard across the first third of his body and flew off.

Liolaemus petrophilus is a medium-sized (< 99 mm SVL) diurnal lizard inhabiting rocky outcrops in Patagonian steppe of the Rio Negro and Chubut Provinces, Argentina (Cei 1986. Museo Regionale di Scienze Naturali Torino, Monographie 4:1–528). Nothing is known about its predators. The Black-bellied Shrike-tyrant is an active diurnal predator that is commonly found in high-Andean steppes, pre-puna and mountain grassland in Argentina

(De la Peña. 1988. Guia de Aves Argentinas. Passeriformes IV. Literature of Latin America, Buenos Aires. 114 pp.). This is the first record of predation of *L. petrophilus* by a Black-bellied Shrike-tyrant.

LIOLAEMUS SANJUANENSIS (NCN). **REPRODUCTION.** *Liolaemus sanjuanensis*, endemic to the Sierra de Pie de Palo in western Argentina, has an ambiguous conservation status as it is listed as a species for which "insufficient knowledge" exists (Lavilla et al. 2000. Categorización de los Anfibios y Reptiles de la República Argentina. Asoc. Herp. Argentina. 97 pp.). Acosta et al. (2004. Herpetol. Rev. 35:171) and Buff et al. (2002 Actas XVI Reunión de Comunicaciones. La Plata, Argentina. 38 pp. [www.fcnym.unlp.edu.ar/xvirch]) recorded observations on body temperature and morphology based on relatively few lizards (N = 31), providing the only published data on the biology of *L. sanjuanensis* biology. Hence, we add the first data addressing reproductive ecology of this species.

We conducted fieldwork in the Sierra de Pie de Palo, Departamento Angaco, Provincia de San Juan (31°22'S, 67°58'W [datum: WGS84]; elev. 2870–2994 m) between 1100 and 1400 h on 8–9 December of 2001. The largely Andean flora is needlegrass (*Stipa*) dominated with patches of the forbs *Fabiana, Baccharis, Adesmia,* and *Senecio* being important (Cei 1980. Hist. Natural. 1:137–140). We obtained data on 31 adult *L. sanjuanensis* captured by revisiting a randomized selection of bushes and low rocks across the study site. Each animal was measured (SVL) and dissected for gonadal/fat body examination. In females, we recorded the number of developing follicles and oviductal eggs, the length of oviductal eggs, and the condition of the oviducts. In males, we recorded the width and length of testes to enable calculation of volume based on Dunham (1983. *In* Huey et al. [eds.], Lizard Ecology, pp. 261–280. Harvard Univ. Press, Cambridge, Massachusetts). Clutch size was determined from the combined number of developing follicles and eggs in the oviducts. All measurements were obtained to the nearest 0.02 mm with Vernier calipers.

Seventeen females ranged in size from 41 to 61 mm SVL; minimum reproductive size was 43 mm, and 86% of the females had fat bodies. Female body size was correlated with clutch size ($r = 0.60$, $P < 0.05$, N = 14). Clutch size averaged 4.5 eggs (SD = 2.87, range: 6–3 eggs, N = 5). The size average of developing follicles was 6.32 mm (SD = 2.24, range: 2.5–8 mm, N = 5), whereas the average length of eggs was 12 mm (SD = 4.6, range: 8–15 mm, N = 5).

Fourteen males ranged in size from 35 to 60 mm SVL, averaging 55 mm SVL. Testicular volume was positively correlated with body size ($r = 0.60$, $P < 0.01$, N = 15), and 56% of the males had fat bodies.

Our data indicate that *L. sanjuanensis* is reproductive in December, although seasonal data are needed to establish the extent of the seasonal interval. Based on the simultaneous presence of developing follicles and oviductal eggs, more than one clutch a year is anticipated. Clutch and egg size data agree with Cei (1986. Reptiles del Centro, Centro-oeste y Sur de la Argentina. Herpetofauna de Zonas Áridas y Semiáridas. Museo Regionale di Scienze Naturali Torino. Monografie IV. 527 pp.), who provided data for one female. The mean clutch size of *L. sanjuanensis* is numerically similar to *L. darwinii* (mean: 4.9, range: 2–8, N = 40) and *L. riojanus* (mean: 4.2, range: 3–6, N = 15) (Blanco et al. 2001. Actas de Resúmenes IV Congreso Argentino de Herpetología, pp. 26–27; Blanco et al. 2003. Actas de Resúmenes XVII Reunión de Comunicaciones Herpetológica, 31 pp.); *L. koslowskyi* (mean: 4.2, range: 3–9, N = 53) (Aun et al. 1993. Cuad. Herpetol. 12:1–9); *L. saxatilis* (mean: 5.6, range: 4–7, N = 47) (Juarez 2002. Estado de Conservación de un Ensamble Herpetológico. Tesis de Licenciatura inédita. Universidad Nacional de Río Cuarto. 63 pp.); and *L. wiegmanni* (mean: 4.6, range: 4–5, N = 19), *L. multimaculatus* (mean: 4.2, range: 3–7, N = 29) and *L. gracilis* (mean: 4.7, range: 4–6, N = 19) (Vega 1999. Ecología de Saurios Arenícolas de las Dunas Costeras Bonaerenses. Tesis doctoral, inédita, Universidad Nacional de Mar del Plata. 102 pp.). Reproductive activity also takes place in December for all these species, suggesting spring–summer oviposition.

Submitted by **JOSE ALBERTO MARINERO, JUAN CARLOS ACOSTA, RICARDO BUFF,** and **PABLO GOMEZ**, Departamento de Biología e Instituto y Museo de Ciencias Naturales, Facultad de Ciencias Exactas, Físicas y Naturales, Universidad Nacional de San Juan, Avenida España 400(n), Caixa Postal 5400, San Juan, Argentina; e-mail (JAM): jamarineroar@yahoo.com.ar.

OLIGOSOMA OTAGENSE (Otago Skink). **PREDATION.** *Oligosoma otagense* is one of the largest and rarest lizards in New Zealand (Whitaker and Loh 1995. Otago Skink and Grand Skink Recovery Plan (*Leiolopisma otagense* and *L. grande*). Threatened Species Recovery Plan No. 14, Department of Conservation, Threatened Species Unit, Wellington, New Zealand, 40 pp.) and is now afforded the highest protection status in New Zealand: 'Nationally Critical' (Hitchmough, Department of Conservation, pers. comm.). Along with habitat loss and degradation, predation is one of the greatest threats to these skinks. Predators known to feed on lizards in the Central Otago area include a number of introduced mammals such as feral cats (*Felis catus*), ferrets (*Mustela furo*), stoats (*M. erminea*), weasels (*M. nivalis*), and hedgehogs (*Erinaceus europaeus*) (Baker 1989. Aspects of Mammalian Predator Ecology Co-inhabiting Giant Skink Habitat. MSc Thesis. University of Otago. 97 pp.; Middlemiss 1995. Predation of Lizards by Feral House Cats (*Felis catus*) and Ferrets (*Mustela furo*) in the Tussock Grassland of Otago. MSc Thesis. University of Otago. 120 pp.; Whitaker and Loh, *op. cit.*). Though skink remains have been found in the stomachs of some *M. erminea* (King and Moody 1982. NZ J. Zool. 9:57–80), implicating them as a possible predator of the large *O. otagense*, no direct observations of *M. erminea* attacks on the *O. otagense* in Central Otago have been made until now.

At 1142 h on 22 January 2004, while conducting a telemetry study on *O. otagense* at Macraes Flat (45°27'12.5"S, 170°26' 53.6" E [datum: WGS84]; ca. 600 m elevation), I observed a *M. erminea*

attack on two of my telemetered skinks. The male-female pair of adults (122 mm and 102 mm SVL, respectively) was basking on a rock outcrop when the *M. erminea* bolted from the surrounding tussock ca. 10 m away and lunged for them. The skinks immediately backed into a crack, the nearest refugia on the rock where they were basking, and the *M. erminea* ran off along the streambed without attempting to extract the lizards from the crack. It took ca. 40 min. for the male to emerge and move to a deeper crack. The female waited ca. 60 min. after the attack before emerging to bask. When tracking the pair the following day, they were found to have crossed a stream (ca. 350 mm wide and ca. 150 mm deep) and moved to a rock with a deep crevice which was 21.4 m from the original site of the attack. Based on telemetry data (JMG, unpubl.data), *O. otagense* make average daily movements of 5.96 m and rarely cross water. A large movement such as this and with the two skinks in conjunction was probably induced by the *M. erminea* attack.

I thank the New Zealand Department of Conservation for their logistical support during this research, and Simon Madill and James Reardon for comments on the manuscript. The Joanna Jackson Goldman Memorial Prize provided funding.

PHELSUMA ORNATA (Ornate Day Gecko). **TAIL LOSS.** *Phelsuma ornata* is a small (max size ~53 mm SVL) member of a largely diurnal genus of brightly colored geckos found in the western Indian Ocean region. Endemic to Mauritius and nearby offshore islands (Vinson and Vinson 1969. Mauritius Inst. Bull. 6:203–320), *P. ornata* is a generalist with a broad diet. It eats insects, pollen, nectar, and fruits (Vinson and Vinson, *op. cit.*; Nyhagen et al. 2001. J. Trop. Ecol. 17:755–761), and adults have been seen eating juvenile *P. ornata* (N. Cole, K. Beer, pers. comm.) and juveniles of introduced house geckos (*Hemidactylus frenatus* and *Gehyra mutilata*) (Vinson and Vinson, *op. cit.*). Often, one finds *P. ornata* with the whole tail or parts of it missing, conditions usually ascribed to conspecific fights or failed predation attempts. During a sampling of the diet of *P. ornata* on Ile Aux Aigrettes, tails of other *P. ornata* were found in 4 of 91 geckos flushed (N. Cole, pers. comm.). Losing the tail generally carries a significant cost (loss of stored nutrients) for lizards, and can have severe consequences (Ballinger and Tinkle 1979. J. Herpetol. 13:374–375) for island-dwellers, where resources often are scarce or unpredictable. Hence, here I report a most unusual case of tail-loss in *P. ornata* from Round Island, a 219-ha volcanic cone rising to 300 m some 22 km N of Mauritius.

At ca. 1000 h on 25 March 2005, I observed a large (ca. 50 mm SVL) male *P. ornata* on the underside of a leaf of a small Bottle-palm (*Hyophorbe lagenicaulis*). The gecko remained still for ca. 5 minutes, upside-down, with its tail flat up against the leaf. Suddenly, the tail went limp, drooping downwards. The gecko reacted immediately to this movement, as they do whenever an insect lands or moves close to them; it twisted back along its right side, grabbed hold of its tail near the base, and ripped it off with one swift move. The tail immediately started twitching violently in the gecko's mouth (Fig. 1). The camera flash, perhaps combined with the movements of the tail, may have caused the gecko to drop the tail. The gecko then quickly disappeared into the dense palm fronds along the trunk's central axis. I picked up the tail, which continued to twitch for about a minute.

FIG. 1. Male *Phelsuma ornata* with its own tail in its mouth.

How the gecko might have handled the tail if undisturbed is unclear. This incident might simply represent a novel, but rare, response to the sudden downward movement of the tail as it became limp, which caused the gecko to view it as live prey. Alternately, self-autotomy might be a regular behavior, the context of which remains to be understood. Only further observations will allow distinguishing between these alternatives.

I thank the Mauritian Wildlife Foundation and the Mauritius National Parks and Conservation Service for permission to join the expedition, and Luke Harmon, Nik Cole, Alfredo Valido, and Marc Hayes for useful suggestions.

PHYLLOPEZUS POLLICARIS (NCN). **REPRODUCTION.** Little is known about native Brazilian geckos (Colli et al. 2003. J. Herpetol. 37:694–706). *Phyllopezus pollicaris*, a large-bodied saxicolous gekkonid, has a broad geographic distribution in South America in open habitats (Pianka and Vitt 2003. Lizards: Windows to the Evolution of Diversity. University of California Press, Berkeley. 333 pp.). Data on this species are available only from northeastern and southeastern Brazil. Here we provided reproductive data for *P. pollicaris* from western Brazil.

Observations were made during a study conducted from May 2003 to April 2004 near the municipality of Corumbá (19°10'49"S, 57°32'17.2"W [datum: WGS 84]; elev. 117 m), Mato Grosso do Sul state. Terrestrial bromeliads and patches of dry forest on a rocky substrate characterize the area. We took substrate temperature data randomly from both bromeliads (N = 169) and surrounding rocks (N = 169) once monthly in each hour between 0600 and

1800 h. We compared temperatures between bromeliads and rocks with a standard t-test and the variance in temperatures between the two habitats with an F-test. Means presented appear ± SD.

We captured one gravid female (70.9 mm SVL) in 28 May 2003 with two eggs (mean length: 13.8 mm; mean width: 10.2 mm) and one well-developed follicle (length: 6.0 mm; width: 4.6 mm). The female was found under a terrestrial bromeliad (*Deuterochomia* sp.). We observed a juvenile on 26 February 2004 under a fallen log. We also found a nest in a terrestrial bromeliad on 13 April 2004 with 6 eggs (mean length: 14.8 ± 0.2 mm; mean width: 11.1 ± 0.3 mm; mean volume; 953 ± 53 mm^3). The nest was positioned under a dead bromeliad on a shallow and dry soil. Temperatures in bromeliads averaged lower (mean = 31.4 ± 4.73°C) and had a narrower range (18-43.4°C) than temperatures from surrounding rocks (mean = 37.2 ± 7.9°C; t-test: 18.4, df = 168, $P < 0.0001$; range = 19–58°C; F test: 2.788, $P < 0.0001$). Four of the eggs were hatched and two were intact. Intact eggs are taken to the laboratory for incubation and after fungal attack were opened to verify species identification.

Our data imply that terrestrial bromeliads might have microhabitats thermally better suited to incubation than rocks. Our observations also indicate that *P. pollicaris* in western Brazil appear to have a clutch size of two and communal nesting similar to *P. pollicaris* from northeastern (Vitt 1992. *In* Hamlett [ed.], Reproductive Biology of South American Vertebrates, pp. 135–149. Springer-Verlag, USA) and southeastern Brazil (Righi et al. 2004. Herpetol. Rev. 35:395–396).

We thank Franco L. Souza and Marc P. Hayes for suggestions on the manuscript. RWA also thanks to CAPES for a fellowship.

CUNHA-AVELLAR**, Departamento de Ciências do Ambiente, Laboratório de Zoologia, Campus de Corumbá, Universidade Federal de Mato Grosso do Sul. Av. Rio Branco, 1270, Caixa Postal 252, CEP 79301-970, Corumbá, MS, Brazil.

SCELOPORUS GRAMMICUS (Mesquite Lizard). **CANNIBALISM.** Cannibalism is well known among lizards (Luiselli et al. 1999. J. Zool. 247:127–131; Kohlsdorf et al. 2004. Herpetol. Rev. 35:398; Perez Z. 2005. Herpetol. Rev. 36:63), often as a response to space limitation and group social structure (Kohlsdorf et al., *op. cit.*). However, this behavior is unreported in *Sceloporus grammicus*, a sceloporine widespread in north-central Mexico (Sites et al. 1992. Bull. Am. Mus. Nat. Hist. [213]:1–95). Hence, we provide an observation of cannibalism in *S. grammicus* from the state of Hidalgo, Mexico.

At 1430 h on 22 April 2005 (sunny, 28°C air temperature), while studying lizard populations in an oak-pine and juniper association at La Estanzuela (20°10'N, 98°45'W [datum: WGS84]; elev. 2700 m), we observed an adult female (48 mm SVL, 2.65 g) *S. grammicus* eating a conspecific neonate (22.3 mm SVL, 0.31 g). The neonate was basking on a rock near the female when the female noticed it, and made a sudden rush grabbing the neonate by the midbody. The female then maneuvered the neonate so it could swallow it head first and consumed it over the next 3 min. We collected the adult lizard after it had eaten, and sacrificed it to examine its gut contents. Twenty-five minutes after ingestion, the neonate was intact.

Both specimens (EST-ABR-3-2005, EST-ABR-3.1-2005) are deposited in the Centro de Investigaciones Biológicas (CIB), Universidad Autónoma del Estado de Hidalgo. We acknowledge support for our research on lizard populations from SEP-PROMEP-1103.5/03/1130, Programa Institucional de Investigación (PII) of the Universidad Autónoma del Estado de Hidalgo, UAE-DIP-ICBI-AAB-020, and thank Marc P. Hayes for his comments.

P. 1-69 Plaza Juárez, C. P. 42001, Pachuca, Hidalgo, México.

THECADACTYLUS RAPICAUDA (Turnip-tail Gecko). **DIET**. *Thecadactylus rapicauda*, a relatively large (95–126 mm SVL) nocturnal gekkonid, occurs in a variety of habitats in Central America, South America, and the West Indies (Savage 2002. Amphibians and Reptiles of Costa Rica, Univ. Chicago Press. 934 pp.). Its diet comprises a wide range of invertebrates (Beebe 1944. Zoologica 29:145–160; Duellman 1978. Misc. Publ. Mus. Nat. Hist. Univ. Kansas 65:1–352; Vitt and Zani 1997. Herpetologica 53:165–179), and, rarely, lizards (*Sphaerodactylus*, Beebe, *op. cit.*; *Anolis*, Malhotra and Thorpe 1999. Reptiles and Amphibians of the Eastern Caribbean, Macmillan Educ. Ltd., London). Here, we augment the prey range of *T. rapicauda* with a report of predation on a leptodactylid frog, *Eleutherodactylus johnstonei* from Grenada.

At 1907 h on 15 February 2005, we encountered an adult (ca. 85 mm SVL) *T. rapicauda* eating an adult (ca. 20 mm) *E. johnstonei* in an area of mixed orchard trees and native forest at Pearls, St. Andrew Parish, Grenada (12°08.879'N, 61°36.765'W [NAD27 (Caribbean)]; elev. 5 m). The lizard was 2.0 m above the ground, oriented head down on a vertical branch of a tree of undetermined species. The frog was being ingested posterior-first. *Eleutherodactylus johnstonei* is common at Pearls (Germano et al. 2003. Carib. J. Sci. 39:68–76; pers. observ.) and we observed additional individuals in the tree where the predation episode occurred. To our knowledge, this is the first record of *T. rapicauda* consuming an anuran.

SERPENTES

AGKISTRODON PISCIVORUS LEUCOSTOMA (Western Cottonmouth). **MORPHOLOGY**. Congenital tail loss has been reported in several species of pit-viper, particularly rattlesnakes (e.g. Klauber 1972. Rattlesnakes. Their Habits, Life Histories, and Influence on Mankind. Univ. California Press, Berkeley, California.

740 pp.; Holycross 2000. Herpetol. Rev. 31:177–178; Christman et al. 2004. Herpetol. Rev. 35:62). On 9 August 2004 I collected a male *Agkistrodon piscivorus leucostoma* (570 mm SVL, 65 mm tail length; 23 subcaudal scutes) at the Old Sabine Bottom Wildlife Management Area, ca. 5 km NE of Lindale, Texas, USA. Gloyd and Conant (1990. Snakes of the *Agkistrodon* Complex. Society for the Study of Amphibians and Reptiles, Oxford, Ohio. 614 pp.) report that male *A. p. leucostoma* have 38–53 (mean = 44.3) subcaudal scutes. Tail length and the number of subcaudal scutes suggests that this snake's tail was about half of typical length. I measured 37 *A. p. leucostoma* (males = 16; females = 21) at this site from November 2002 to August 2004 and this was the only individual with a tail abnormality. There was no evidence of scarring or injury, suggesting this abnormally short tail might be a congenital defect.

Submitted by **PAUL M. HAMPTON**, Department of Biology, University of Texas at Tyler, 3900 University Boulevard, Tyler, Texas 75799, USA.

AGKISTRODON PISCIVORUS LEUCOSTOMA (Western Cottonmouth). **REPRODUCTION**. The reproductive ecology of *Agkistrodon piscivorus* is well documented. The smallest gravid female previously reported was 455 mm SVL (Burkett 1966. Univ. Kansas Publ. Mus. Nat. Hist. 17:435–491). In northeast Texas, gravid females average 579 mm SVL with the smallest being 540 mm SVL (Ford 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 167–177. Eagle Mountain Publ., Eagle Mountain, Utah). Litter size averages five offspring and neonates average 207 ± 8.9 mm SVL and 14.9 ± 2.49 g mass (Ford 2002, *op. cit.*). Here, we report reproductive data for a short female *A. piscivorus leucostoma* from northeast Texas.

On 15 August 2004 we collected a gravid female (490 mm SVL) from Old Sabine Bottom Wildlife Management Area, Smith County, Texas, USA. On 29 August she gave birth to four offspring, one of which did not emerge from its embryonic sac. The stillborn weighed 10.5 g and measured 19.7 SVL, and 23.6 TL. The three surviving offspring averaged 206.7 ± 12.6 mm SVL (range 195–220 mm), 246.7 ± 14.4 mm TL (236–263 mm), and 10.9 ± 1.2 g mass (9.5–11.7 g). The post parturition mass of the female was 121 g therefore the relative clutch mass was 35.7%. Although the female's mass after parturition was much less than the previously reported mean for *A. piscivorus* in northeast Texas (213 ± 19.6 g), clutch size is comparable with other females from the region. This observation agrees well with Ford et al. (2004. Southwest. Nat. 49:465–471) who found no correlation between female SVL and clutch size in this species. This small female's low post-partum mass but normal clutch and offspring size suggests she contributed a larger percentage of her energy intake to her clutch than would a larger female.

Submitted by **PAUL M. HAMPTON** and **NEIL B. FORD**, Department of Biology, University of Texas at Tyler, 3900 University Boulevard, Tyler, Texas 75799, USA.

AMPHIESMA MIYAJIMAE (Taiwanese Keelback). **REPRODUCTION**. *Amphiesma miyajimae* is a rare, oviparous natricine snake, endemic to mountainous areas below 1000 m in Taipei County, northern Taiwan (Maki. 1931. A Monograph of the Snakes of Japan. Daiichi Shobo Publish, Tokyo, Japan. 51 pp.). On 17 July 1996 we found an *A. miyajimae* (Dept. of Natural Resources, National Ilan University; NIU-NR-021004; 428 mm SVL) dead in a roadside ditch in Sze-Leng, Tao-Yuan County at 720 m elev. The specimen was gravid and contained three completely developed eggs ranging in length from 29.6 to 33.0 mm (mean = 31.0 ± 1.8 mm SD) and in width from 9.8 to 10.4 mm (10.2 ± 0.3 mm). Maki (op. cit.) reported that the eggs of this species are very long and thin (42 x 11 mm, longer than the eggs described herein), but did not report the clutch size or the maternal SVL. Based on the stage of development of the eggs, we presume that oviposition probably would have taken place in late July or early August.

Submitted by **JEAN-JAY MAO**, Department of Natural Resources, National Ilan University. No. 1, Sec. 1, Shen-Non Rd., Ilan, Taiwan 260 (e-mail: jjmao@niu.edu.tw); and **GERRUT NORVAL**, Applied Behavioural Ecology & Ecosystem Research Unit, Department of Nature Conservation, UNISA, Private Bag X6, Florida, 1710, Republic of South Africa.

ANILIUS SCYTALE (False Coralsnake). **REPRODUCTION.** *Anilius scytale*, the only species in the Aniliidae, is restricted to northern South America. Adults range up to 1184 mm total length (TL) and females are reproductively mature at 350 mm TL (Dixon and Soini 1986. The Reptiles of the Upper Amazon Basin, Iquitos Region, Peru. Milwaukee Public Museum, Milwaukee. 154 pp.). Little information on ecology or life history of this species has been published, despite its broad distribution.

On 05 December 2003 we collected an adult female (762 mm TL, 149.28 g, young not included in her weight) dead on the road ca. 30 km N of Manaus on Highway AM-010 in Amazonas state, Brazil. She was found with 20 live young surrounding her corpse. Upon dissection, four additional young, one of them malformed, were found inside the female. The 24 neonates averaged 182.8 ± 0.72 (SD) mm TL (range = 165.8–195.1) and averaged 1.65 ± 0.32 (SD) g (range = 1.11–2.38) in weight. The combined mass of the neonates was 39.56 g.

Neonatal total lengths reported here are within the range of previously reported observations (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150; Cunha and Nascimento 1981. Boletim do Museu Paraense Emílio Goeldi 109:1–20). However, clutch size reported here is considerably larger than previously published records (range 4–15; Cunha and Nascimento *op. cit.*; Dixon and Soini, *op. cit.*; Martins and Oliveira, *op. cit.*). Interestingly, this female is ca. 15% shorter than a snake (927 mm TL, 181 g) that gave birth to 15 young (Martins and Oliveira, *op. cit.*), although relative clutch mass was lower in our snake (27%) as compared to the other (29%), and the young in the clutch of 15 were also larger (206–234 mm; Martins and Oliveira, *op.cit.*). The largest reported gravid female (1184 mm TL) contained only 6 embryos (Dixon and Soini *op. cit.*). The female and her young are deposited in the collection of Amphibians and Reptiles of the Instituto Nacional de Pesquisa da Amazônia (INPA-H 11364-11388).

BOA CONSTRICTOR CONSTRICTOR (Boa Constrictor) and ***BOTHROPS JARARACA*** (Jararaca). **DIET**. During a radiotelemetric study of Grey Four-eyed Opossum (*Philander frenata*) and Bare-tailed Woolly Opossum (*Caluromys philander*) in an Atlantic Forest fragmented landscape in southern Poço das Antas Biological Reserve (22°34'S, 42°15'W), Brazil, we observed predation by *Boa constrictor constrictor* and *Bothrops jararaca*. Additional information on these habitats is provided in Viveiros de Castro and Fernandez (2004. Biol. Conserv. 119:73–80). Two of seven radio-collared *P. frenata* were eaten by *B. c. constrictor*. On 27 November 2001 we located one of our male *P. frenata* (335 g) inside a *B. c. constrictor* (ca. 7 kg and ca. 2.5 m TL). On 19 December 2002 we located a second male *P. frenata* (515 g) inside a second, smaller *B. c. constrictor*. One of four radio-collared *C. philander* was eaten by *B. jararaca*. On 4 June 2003 we located a female *C. philander* (ca. 185 g) inside a *B. jararaca*, at a location where this opossum had already been located, probably foraging. The radiotransmitter was found two months later in the feces of the snake ca. 6 m away from the place where the pitviper had been seen last. Radio-telemetry probably did not increase the risk of being preyed upon by these snakes, because both *B. c. constrictor* and *B. jararaca* are principally ambush hunters (Hartmann et al. 2003. Phyllomedusa 2:35–41; Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publ., Eagle Mountain, Utah) and we postulate that radio-collars might even reduce opossum activity and probability of predation. The high frequency of predation we observed on radio-collared opossums suggests that snake predation might be an important source of mortality in these populations. Yet, to the best of our knowledge, these are the first records of *B. c. constrictor* predation on *P. frenata* and of *B. jararaca* predation on *C. philander*.

We thank Lígia Pizzatto for suggestions, Idea Wild for equipment, Fundação O Boticário de Proteção à Natureza, The Nature Conservancy, CNPq, FAPERJ and CAPES for grants and financial support.

BOTHROPS ATROX (Common Lancehead). **DIET**. *Bothrops atrox* has a broad and ontogenetically variable diet that includes centipedes, fishes, frogs, lizards, snakes, birds, and small mammals (*see* Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150, and citations therein). On 30 March 2003 at 0930 h we captured a juvenile *B. atrox* (281 mm SVL, 12 g after prey removal) in a pasture near Cacoal (11°26'S, 61°26'W), Rondônia, Brazil. Upon dissection, we found a *Leptodactylus fuscus* (Leptodactylidae; 55 mm SVL, 7 g) that had been ingested head-first in the snake's stomach. This is the first report of *L. fuscus* in the diet of *B. atrox*. The snake was deposited in the herpetological collection of Faculdade de Ciências Biomédicas de Cacoal (FACIMED 036).

Submitted by **LÍLIAN CRISTINA MACEDO-BERNARDE** and **PAULO SÉRGIO BERNARDE**, Laboratório de Ecologia Animal, Faculdade de Ciências Biomédicas de Cacoal - FACIMED, Avenida Cuiabá nº 3.087, Jardim Clodoaldo, Cacoal – RO, 78.976-005, Brazil.

CONTIA TENUIS (Sharp-tailed Snake). **REPRODUCTION**. The reproductive biology of *Contia tenuis* is poorly known. Two reports suggest that eggs are laid in summer and hatch in fall (Brodie et al. 1969. Herpetologica 25:223–227; Cook 1960. Herpetologica 16:163–173). However, to the best of our knowledge, copulation has not been observed in the wild or captivity. At 1241 h on 6 March 2005, we found two *C. tenuis* copulating under a wooden board near a meadow/forest ecotone in Briones Valley (37°55'31"N, 122°10'00"W), Contra Costa County, California, USA. The day was unseasonably warm (19.4°C). When disturbed from their location near the board's edge, the pair attempted to flee, but remained connected via the male's intromitted hemipenis. The snakes were not captured or photographed, but we estimate that each was ca. 170–200 mm total length.

Submitted by **JAMES F. PARHAM** and **SARAH E. RIEBOLDT**, University of California Museum of Paleontology, University of California, Berkeley, California 94720, USA; e-mail (JFP): parham@socrates.berkeley.edu.

CROTALUS HORRIDUS (Timber Rattlesnake). **BEHAVIOR.** Although many rattlesnake species probably drink beads of dew or raindrops from their skin, there have been few published observations of rattlesnakes altering their body posture to facilitate water collection in the wild (Ashton and Johnson 1998. Herpetol. Rev. 29:170; Bogert 1927. Nature Mag. 10:297–299; Greene 1997. Snakes: The Evolution of Mystery in Nature. Univ. of Calif. Press, Berkeley. 351 pp.; Schwenk and Greene 1987. J. Herpetol. 21:134–139). On 05 May 2001 we watched a radio-tagged male *C. horridus* drink water from the margins of its tightened coils during a heavy downpour in bottomland forest in western St. Louis County, Missouri, USA. This rattlesnake was observed in a looser coiled position several minutes earlier. The behavior we witnessed is similar to the rain collecting behavior described for the Great Basin Rattlesnake, *Crotalus oreganus lutosus* (Aird and Aird 1990. Bull. Chicago Herpetol. Soc. 25:217); however, we did not witness coiling in anticipation of the approaching storm.

Submitted by **COREY DEVIN ANDERSON**, Department of Biology, Washington University in St. Louis, Campus Box 1137,

One Brookings Way, St. Louis, Missouri 63130, USA; and **WAYNE J. DRDA**, Tyson Research Center, P.O. Box 258, Eureka, Missouri 63025, USA.

DRYMARCHON CORAIS MELANURUS (Indigo Snake). **DIET**. *Drymarchon corais* is a highly polyphagous colubrid (Greene 1997. Snakes: The Evolution of Mystery in Nature. Univ. California Press, Berkeley. 351 pp.) with a wide geographic distribution and eight currently recognized subspecies (McCranie 1980. Cat. Amer. Amph. Rept. 267.1). Of these, *Drymarchon c. melanurus* appears to occupy the broadest range of habitats, ranging from humid rainforest habitats in Yucatan, México through both mesic and xeric areas of Central American and the coasts of Colombia. Although diet probably varies considerably over this broad distribution, information relating locality and dietary information is largely lacking. On 6 December 1998, a dead female *D. c. melanurus* (MHUA 14076, 1100 mm TL) was found on a roadway in the Guajira desert in northern Colombia (11°0'46"N, 72°42'18"W, ca. 160 m elev.) with an adult *Mastigodryas pleei* (Colubridae, MHUA 14077, 900 mm TL) in its digestive tract. It was unclear from these circumstances whether ingestion of the *M. pleei* comprised an incidence of predation or scavenging. Nevertheless, this observation documents sympatry of these taxa in this region and demonstrates that *D. corais* are capable of ingesting snakes of almost the same size. Specimens were deposited in the Museum of Herpetology of the Universidad de Antioquia (Medellín, Colombia).

ERPETON TENTACULATUM (Tentacled Snake). **REPRODUCTION.** Twinning has been reported in a variety of reptiles (Hartdegen 1999. Herpetol. Rev. 30:141). Among the squamates, crocodilians, and chelonians, twinning has been reported only in oviparous species with the exception of Hubert (1985 *In* Gans and Billett [eds.], Biology of the Reptilia Vol. 15, pp. 28–29, John Wiley & Sons, New York) who reported experimentally derived twins in *Lacerta vivipara*. Twinning is easily documented in oviparous species because the number of hatchlings outnumbers the eggs hatched. On 12 May 2003 a female *Erpeton tentaculatum* held in captivity (Oklahoma City Zoo) gave birth to eight neonates, including two stillborn twins. The twins were still connected to a single yolk sac by their individual umbilici (OMNH 41670 and 41671) and are possibly monozygotic. To the best of our knowledge, this is the first documentation of a non-induced twinning event in a live-bearing reptile.

HETERODON PLATIRHINOS (Eastern Hog-nosed Snake). **REPRODUCTION**. On 08 February 2005 at ca. 1430 h we observed two *Heterodon platirhinos* copulating (tails intertwined) in a manner analogous to previously reported mating behavior (e.g., Plummer and Mills 1996. J. Herpetol. 30:80–82). Copulation was visibly confirmed when the female began to drag the male and the male's everted hemipenis was withdrawn from the female. The snakes were observed in a 65-year-old, frequently burned, slash pine (*Pinus elliottii* var. *elliotti*) plantation in Baker County, Georgia, USA. High temperature on this date was ca. 24°C. To our knowledge, the earliest previously reported dates of copulation for *H. platirhinos* in the wild are 19 March (Plummer and Mills, *op. cit.*) and 28 March (Guidry 1953. Herpetologica 9:49–56).

Submitted by **DAVID A. STEEN** (e-mail: David.Steen@jonesctr.org), **SARAH N. BECKER,** and **LORA L. SMITH**, Joseph W. Jones Ecological Research Center, Route 2, Box 2324, Newton, Georgia, USA.

LAMPROPELTIS TRIANGULUM AMAURA (Lousiana Milksnake). **SIZE RECORD**. On 20 July 2004 at 2040 h one of us (TAS) collected a male *Lampropeltis triangulum amaura* DOR on Osburn Road, 0.3 km south of Farm Road 1375 (30°31'29"N, 95°40'55"W, 77 m elev.), Montgomery County, Texas. This specimen (TCWC 88217) measured 901 mm TL (809 mm SVL + 92 mm tail length). The longest *Lampropeltis triangulum amaura* reported prior to this measured 787 mm TL (Boundy 1995. Bull. Chicago Herpetol. Soc. 30:109–122). We thank J. R. Dixon for verifying the subspecific identification.

LIOPHIS LINEATUS (NCN). **REPRODUCTION.** Relatively few data are available concerning the natural history Colombian snakes, especially those that inhabit remote areas. On 11 December 1998, I encountered a female *Liophis lineatus* (MHUA 14075, 708 mm TL) on the Guajira peninsula on the Atlantic coast of Colombia that contained six eggs. I measured three of these eggs and they averaged 29.4 mm in length. The snake was found in a shallow pit near riparian forest (11°0'46"N, 72°42'18"W, ca. 160 m elev.) that also contained several *Bufo marinus*. The Guajira desert receives only ca. 900 mm of rainfall annually, with most falling from April to November, and has a pronounced dry season extending from December to March. This observation suggests that reproduction in *L. lineatus* in this area might be timed such that hatching coincides with the onset of the rainy season. The specimen is deposited in the Museum of Herpetology of the Universidad de Antioquia (Medellín, Colombia).

Submitted by **JUAN MANUEL DAZA-R.**, Department of Biology, 4000 Central Florida Blvd., University of Central Florida, Orlando, Florida 32816, USA; e-mail: juandaza35@hotmail.com.

MICRURUS DECORATUS (Decorated Coralsnake). **DIET.** *Micrurus decoratus* is found in high elevation remnants of endangered Atlantic Forest in the Serra do Mar and the Serra da

Mantiqueira in Brazil. Although little is known of the natural history of this secretive species, Marques (2002. Amphibia-Reptilia 23:228–232) reports 5 prey items (3 *Siphonops* sp. and 2 *Amphisbaena* sp.) from 24 specimens he examined. We examined the stomach contents of 109 museum specimens of *M. decoratus* from São Paulo, Rio de Janeiro, Minas Gerais, and Paraná, Brazil housed in the following collections: Instituto Butantan, São Paulo (IB: 88 specimens), Instituto Vital Brasil, Rio de Janeiro (IVB: 7 specimens), Museu de História Natural Capão da Imbuia, Curitiba (MHNCI: 1 specimen), Museu de Zoologia da Universidade de São Paulo (MZUSP: 7 specimens), and Museu Nacional do Rio de Janeiro (MNRJ: 6 specimens). Three prey items were identified. Two *Siphonops* sp. were in advanced stages of digestion and could not be specifically identified, although we were able to determine that one of these was consumed head-first and the other tail-first. A single *Amphisbaena dubia* (280 mm) was consumed tail-first by a 674 mm SVL *M. decoratus*. These observations offer further evidence that *M. decoratus* feeds primarily on amphisbaenids and caecilians. Carolina Castro-Mello identified the amphisbaenids.

Submitted by **LEVI CARINA TERRIBILE** and **NELSON JORGE DA SILVA JR.**, Centro de Estudos e Pesquisas Biológicas, Universidade Católica de Goiás, Ave. Universitária 1440, Setor Universitário, 74.605-010, Goiânia, Goiás, Brazil (e-mail: levicarina@terra.com.br).

OXYRHOPUS RHOMBIFER SEPTENTRIONALIS (False Coral Snake). **DIET**. *Oxyrhopus rhombifer* is a terrestrial and primarily nocturnal colubrid (tribe Pseudoboini) that occurs in open habitats in South America. Four subspecies are recognized, *O. r. inaequifasciatus*, *O. r. bachmanni*, *O. r. rhombifer*, and *O. r. septentrionalis* (Peters and Orejas-Miranda 1986. Catalogue of the Neotropical Squamata. Part I – Snakes, 2nd ed. Smithsonian Inst. Press, Washington. 174 pp.). Limited data suggest that *O. r. inaequifasciatus*, *O. r. bachmanni*, and *O. r. rhombifer* primarily consume lizards and small mammals (Maschio et al. 2004. Herpetol. Rev. 35:71, and citations therein). However, there is no published information regarding the diet of *O. r. septentrionalis*.

During an investigation of the natural history of a snake community in Cerrado vegetation of Brasília, Distrito Federal, Brazil (15°35'S, 47°50'W), we identified the gut contents of 40 preserved *O. r. septentrionalis* in the Coleção Herpetológica da Universidade de Brasília (CHUNB). Prey remains were removed from both the stomach and hindgut, all snakes and intact prey were measured and weighed, and prey/predator mass ratio (MR) was calculated when possible. Twenty-two *O. r. septentrionalis* (55%) did not contain prey remains and one (2.5%) contained completely unidentifiable prey remains. Identifiable prey remains were found in 17 snakes (42.5%) and included lizards (N = 15; 88.2%) and small mammals (N = 2; 11.8%). A diverse assemblage of lizards was represented, including six tropidurids, four gymnophtalmids, three teiids, a polychrotid, and a scincid. Two nearly intact *Tropidurus itambere* (34 mm SVL, 3.5 g; 44 mm SVL, 3.5 g) and two *Tropidurus* sp. (40 mm SVL, 2.5 g; 34 mm SVL, 2.5 g) were discovered in snakes measuring 230 mm SVL (8 g, MR = 0.44), 248 mm SVL (8 g, MR = 0.44), 231 mm SVL (7 g, MR = 0.36), and 255 mm SVL (9 g, MR = 0.28), respectively. Two additional snakes contained the scales of tropidurid lizards that could not be further identified. Two *Micrablepharus atticolus* (both 33 mm SVL, 1 g) were discovered in a 169 mm SVL (4 g; MR = 0.25 each) snake. One *Cercosaura ocellata* (30 mm SVL; 1 g) and one *Colobosaura modesta* (40 mm SVL; 3 g) were eaten by snakes measuring 187 mm SVL (4 g; MR = 0.25), and 200 mm SVL (5g; MR = 0.6), respectively. Three *Ameiva ameiva* (102 mm SVL, 28 g; 106 mm SVL, 38 g; 114 mm SVL, 35 g) were found in the stomachs of snakes measuring 526 mm SVL (45 g, MR = 0.62), 566 mm SVL (53 g, MR = 0.71), and 609 mm SVL (100 g, MR = 0.35), respectively. An *Anolis meridionalis* (no data measure) and a *Mabuya nigropunctata* (80 mm SVL; 12 g) were eaten by snakes measuring 380 mm SVL (24 g) and 557 mm SVL (62 g, MR = 0.19), respectively. A young *Calomys tener* (Rodentia, Sigmodontinae, 60 mm, 5 g) and an unidentified rodent were found in stomachs of snakes measuring 335 mm SVL (14 g, MR = 0.36) and 340 mm SVL (24 g). All prey were ingested headfirst. Linear regression showed a positive correlation between prey SVL and predator SVL ($r^2 = 0.979$; $F_{1,9} = 414.4$; $P = 0.04$).

Our data indicate that *O. r. septentrionalis* feed primarily on lizards, but occasionally eat mammals as well. Further, *O. rhombifer* appears to feed on a great variety of lizards. Two families of lizards, Anguidae and Gekkonidae, which we did not find in our sample, have been reported in the diet of *O. r. rhombifer* (Maschio et al. 2004, *op. cit.*, and citations therein). Our sample indicates that prey SVL (primarily lizards) increases with *O. r. septentrionalis* SVL, as is the case in many snakes (Arnold 2001. *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 87–115, Blackburn Press, New Jersey).

We thank D. O. Mesquita and A. Bezerra for assistance, G. R. Colli for permission to examine specimens, and CAPES for financial support.

OXYRHOPUS TRIGEMINUS (False Coral Snake). **PREY**. *Oxyrhopus trigeminus*, a terrestrial colubrid snake, is widely distributed in Brazil (Peters and Donoso-Barros 1986. Catalogue of the Neotropical Squamata, Part I, Snakes. Smithsonian Institution Press, Washington, DC.). Although a few reports suggest it preys mainly on lizards and small mammals (Amaral 1978. Serpentes do Brasil. Iconografia Colorida. - Edições Melhoramentos, Editora da Universidade de São Paulo; Vitt and Vangilder 1983. Amphibia-Reptilia 4:273–296), its diet remains poorly known. Vitt and Vangilder (*op. cit.*) report that of nine snakes they examined, seven contained prey, including the rat *Bolomys lasiurus* and three lizard species: *Cnemidophorus ocellifer*, *Ameiva ameiva*, and *Tropidurus torquatus* (= *T. hispidus;* see Rodrigues 1987. Arq. Zool., São Paulo 31:105–230). On 28 November 2002 at 0700 h we found an adult male *O. trigeminus* (544 mm SVL, 56 g) in Restinga de Jurubatiba National Park, (22°16'53S, 41°39'20W), Quissamã, north of Rio de Janeiro State, Brazil. The snake was on

the ground near the base of a set of bromeliad ramets and appeared to have recently fed. We collected the snake and transported it to the laboratory. En route to the laboratory, the snake regurgitated a male *Tropidurus torquatus* (91 mm SVL, 30 g). In light of recent taxonomic changes (see above), *T. torquatus* represents a novel prey record for *O. trigeminus*. The snake (MNRJ 9850) and lizard (MNRJ 9851) are deposited in the Museu Nacional, Rio de Janeiro. Supported by grant of the Programa de Pesquisas Ecológicas de Longa Duração - PELD/CNPq/Site 05/ Jurubatiba.

PSAMMOPHIS NAMIBIENSIS (Namib Sand Snake). **BEHAVIOR.** Diurnal, slender, and fast-moving, the Namib Sand Snake (*Psammophis namibiensis*, see Broadley 2002. Afr. J. Herpetol. 51:83–119) occurs in hot and sandy areas throughout the Namaqualand Region (Namibia) to the north of the Cape Province, South Africa (Branch 1998. Field Guide to Snakes and other Reptiles of Southern Africa. Struik, Cape Town. 376 pp.; Bauer et al. 1993. Madoqua 18:117–145). On 23 July 2004 at 1100 h near Fort Khan (55 km W of Usakos, Erongo Region, Western Central Namibia, 15°10'E, 22°20'S), in an arid savanna of *Acacia erioloba*, we watched a *P. namibiensis* (ca. 900 mm TL). During these observations, a Namaqua Sand Lizard (*Pedioplanis namaquensis*; 45–50 mm SVL) moved 120 cm away from the snake in the shade of an Acacia tree. The snake stopped, raised the head 10 cm above the ground, and visually tracked the moving lizard. The lizard climbed into the lower branches of the acacia, where it was struck and grasped at mid-body by the snake. The snake immediately began to "chew," alternating both maxillaries, to sink the rear fangs of this opistoglyphous snake more securely into the prey. After 90 seconds, the lizard ceased struggling and appeared to be dead. After another 130 seconds the snake dropped the lizard, moved to the head of the lizard (*sans* tongue flicking), and began to ingest it head-first. In 110 seconds the lizard was completely swallowed. The snake moved to the tree trunk and began to bask with only the portion of the body containing the lizard exposed to sunlight (exhibiting regional body thermoregulation; Peterson et al. 1993. *In* Seigel and Collins [eds.], Snakes, Ecology and Behavior, pp. 241–314. McGraw-Hill, New York).

PSEUSTES SULPHUREUS (South American Puffing Snake). **DIET.** *Pseustes sulphureus* is a diurnal, arboreal, and oviparous snake that occurs in the neotropical region, from Mexico to southeastern Brazil, where it seems to be somewhat rare (Amaral 1978. Serpentes do Brasil. Melhoramentos/EDUSP, São Paulo, 247 pp.). It probably feeds primarily on birds and their eggs, but appears to have a varied diet that includes amphibians, lizards, bats and other small mammals (Amaral op.cit; Freitas 2003. Serpentes Brasileiras. Malha-de-Sapo Publicações e Consultoria Ambiental Lauro de Freitas. 206 pp.; Marques et al. 2001. Serpentes da Mata Atlântica: um Guia Ilustrado para a Serra do Mar, Editora Holos, São Paulo. 184 pp.; Rufino 1999. Herpetol. Rev. 31:103). Rivas and Kane (2003. Herpetol. Rev. 34:72) provide the only specifically identified avian prey, a *Crypturellus soui* (Little Tinamou).

At 1210 h on 17 November 2004 we found a subadult female *P. sulphureus* entering a *Stelgidopteryx ruficollis* (Southern Rough-winged Swallow) nest at the Reserva Ecológica de Guapiaçú (22°24'619"S, 42°44'253"W, 250 m elev.) in Cachoeiras de Macacu municipality ca. 150 km W from Rio de Janeiro, Brazil. The nest was located at the end of a tunnel about 5 cm in diameter and 41.5 cm long. When first sighted, only the anterior third of the snake was inside the nest. The snake remained in this position for ca. two minutes. It then entered the nest completely and about a minute later its head emerged at the entrance. We then captured the snake and forced it to regurgitate an intact *S. ruficollis* nestling (20.5 g), which it had swallowed head-first. The eaten nestling was one of a brood of three; the two remaining nestlings were found alive inside the nest after the predation event. The snake measured 92.8 cm SVL, weighed 150 g (excluding the prey), and was cataloged into the Rio de Janeiro Zoological Garden (FRZ12533). Our observation suggests that *P. sulphureus* is an active forager.

PTYAS MUCOSUS (Oriental Rat Snake). **ECTOPARASITES.** On 18 June 2003 firefighters gave us an adult female (ca. 1600 mm TL) *Ptyas mucosus* captured at a school in Chiayi County, Taiwan (23°27'08"N, 120°27'18"E). Four ticks were imbedded between the dorsal scales; one ca. 300 mm and the other three ca. 500 mm from the snout. The ticks were removed and identified as adult female *Amblyomma cordiferum*. Immature stages of this tick species feed on rodents, and adults have been reported from the King Cobra (*Ophiophagus hannah*) and the Reticulated Python (*Python reticulatus*) (Barnard and Durden 2000. A Veterinary Guide to the Parasites of Reptiles. Vol. 2. Krieger Publishing, Florida. 107 pp.). To our knowledge, this is the first recorded case from Taiwan of *P. mucosus* being a host for this tick species.

We thank Pi-Hwa Su for preparing electron microscope images of the ticks and Gennady Kolonin for verifying tick identification.

SEMINATRIX PYGAEA (Black Swamp Snake). **REPRODUCTION.** Previous reports of litter size in *Seminatrix pygaea* range from 2 to 15 and were determined primarily by counting the number of enlarged follicles or embryos during palpation or dissection (Gibbons and Dorcas 2004. North American Watersnakes: A Natural History. University of Oklahoma Press, Norman. 438 pp.). During July 2004, three of 15 pregnant females gave birth to record size litters (16, 19, and 22). Pregnant *S. pygaea* were collected between 27 May and 1 June 2004 from Ellenton Bay (Savannah River Site, South Carolina) using aquatic minnow traps. All snakes were housed individually in the laboratory at 27°C and offered salamander larvae (*Ambystoma talpoideum*) every 7–10 days until they gave birth. Within 24 h of parturition I measured the mass (nearest 0.01 g), SVL (nearest mm), and tail length (nearest mm) of the mother and all neonates. Total litter mass (TLM, all neonates together) was measured and used to calculate reproductive investment (relative clutch mass) by dividing the post-partum maternal mass by the total litter mass (Shine 1980. Oecologia 46:92–100). All neonatal values are presented as mean ± 1 SE. Because of their small size at birth, it was not possible to safely sex the neonates by probing; therefore I relied on relative tail length to sex the neonates (Dodd 1993. Can. J. Zool. 71:1281–1288). On 17 July a female (post-partum mass = 33.90, SVL = 363) gave birth to 22 neonates (TLM = 28.36, mass = 1.29 + 0.02; SVL = 108.9 ± 0.62; 9 Females: 13 Males). On 20 July a litter of 16 neonates (TLM = 22.41, mass = 1.40 ± 0.03; SVL = 112.8 ± 0.75; 7F: 9M) was born to a second female (post-partum mass = 29.23, SVL = 354). Lastly, on 25 July a female (post-partum mass = 33.25, SVL = 383) gave birth to 19 neonates (TLM = 18.81, mass = 0.99 ± 0.02; SVL = 101.5 ± 0.93; 13F: 6M). All three mothers expended a large reproductive effort as indicated by high relative clutch masses (0.84, 0.77, and 0.57 respectively). None of the litters contained stillbirths and all snakes were returned to their original point of capture.

Understanding species-habitat associations are imperative for wildlife management (Cross and Petersen 2001). Although several causes of global amphibian declines are suggested, habitat modification is implicated in many cases (Daniels 1991; Fisher and Shaffer 1996; Lips 1998, 1999; Richards et al. 1993). Because amphibians show site fidelity and have limited dispersal capabilities, forest fragmentation and modification could effectively disrupt their population structures (Marsh and Pearman 1997; Osawa and Katsuno 2001) and cause local extinctions of species (Blaustein et al. 1994). For example, frogs belonging to the genus *Leptodactylus* have been reported to be more abundant in larger patches of forest than in smaller patches (Marsh and Pearman 1997). In particular, amphibian populations relying on forest microhabitat features might undergo rapid decline because of disturbances.

Because of the rapid conversion of Indian forests to plantations, the status of Indian forest amphibians is of concern (Daniels 2003; Reddy et al. 2002). In south India, forest practices have modified the once contiguous forests of the Western Ghats into fragments resulting in isolation of habitats, disrupted microhabitat and altered vegetation structure. However, information on Indian amphibians is sparse (Oommen et al. 2000). Among Indian frogs, Bull Frog (*Hoplobatrachus tigerinus)* populations appear to have declined from paddy fields (pers. obs.). This might be due in part to the export of frog legs (now banned) and the application of insecticides and pesticides used in rice cultivation (Mohanthy-Hejmadi and Dutta 1981). Reports have indicated a threat by habitat fragmentation to torrent frogs of the genera *Nyctibatrachus* and *Melanobatrachus* (Gupta 1998). Surveys in modified habitats have recorded complete absence of several species of the genus *Micrixalus,* although they are present in the adjoining forest habitats (Daniels 2003; Krishna et al. 2005). The disturbed sites of Kudremukh National Park in the central Western Ghats have shown a 50% reduction in amphibian species richness when compared to undisturbed forest sites (Krishnamurthy and Hussain 2004).

We examined forest habitat associations of the Bicolor Frog, *Clinotarsus curtipes* (Ranidae, Hyloraninae) in three habitat types: native forest, coffee and cardamom plantations. This frog breeds in streams and ponds with tadpoles occupying aquatic habitats for over a year, after which frogs inhabit the litter and rock crevices in forest floors of the Western Ghats, South India (Daniel 2002). Our results provide insights to the potential effects of native forest conversion to plantation on this species.

We surveyed frogs and habitats at Bisale Forest Reserve and adjoining plantations (12°44'N; 75°43'E) in the South Indian state of Karnataka. The study area was a 366-ha forest ranging in elevation from 145 to 940 m. The area receives heavy rainfall (annual average rainfall: 4.5 m) from southwest monsoon winds for six months a year. The vegetation type is semi-evergreen (Champion and Seth 1968), dominated by *Dipterocarpus indicus, Kingiodendron pinnatum,* and *Humboldtia brunonis* (Pascal 1988). Many perennial hill streams, shallow ponds, and freshwater swamps exist and offer ideal locations for amphibians. The periphery of these protected forests are highly fragmented and experience high human disturbance from crop cultivation, power generation projects, road construction, tree harvest, and cattle grazing. The forests are fragmented in lower elevations by arecanut (*Areca catechu*), coconut (*Cocos nucifera*), and rubber (*Hevea brasiliensis*) plantations and at higher elevations by cardamom (*Elettaria cardamomum*) and coffee (*Caffea arebica*) plantations.

We sampled frogs in three adjoining habitats in the high elevations: forest, cardamom plantation, and coffee plantation. Rainfall, elevation, wind speed, and temperature were similar at all three sampling sites. Native forest habitat had not been previously disturbed. Cardamom is grown in the valleys of hilly slopes as an intercrop in the native forest without clearing the undergrowth and forest canopy. Very few cultivation operations are practiced, neither fertilizer nor insecticides are used and undergrowth removal is minimal. Coffee is sparsely shade-grown in India; cultivation involves removal of native canopy and undergrowth, with the application of fertilizers, insecticides, and pesticides to prevent stem bores. These farming practices convert natural forests into modified monoculture plantations.

We searched for frogs using transect sampling (Jaeger 1994), recording frogs within 10 x 4 m transects placed parallel to each other. Based on the habitat sizes, 10 transects were placed in forest and cardamom habitat and 5 in coffee habitat. Transects were sampled from May 2001 to October 2002. Forest habitat transects were sampled fortnightly once from May to December 2001 and monthly once from January to April 2002 resulting in a total of 200 transects in forest habitat (8000 m^2). However, due to the plantation activities, sampling in the other two habitats were not equal. In cardamom habitat we sampled 10 transects monthly once from May 2001 to June 2002 resulting in a total of 140 transects (5600 m^2), and in coffee habitat, 5 transects were sampled from May 2001 to May 2002 for a total of 65 transects (2600 m^2).

Transects were delimited by stakes and nylon chords. Two observers walked transects between 0600 to 0800 h and 1800 to 2100 h to flush frogs. Bicolor Frog sightings were recorded along with microhabitat per sighting (e.g., on litter, under a rock, under canopy, open canopy). Because Bicolor Frogs were not sighted during the post-monsoon and dry seasons, we used only data from May to October 2001 to estimate frog density in all three habitats. Hence, abundance was calculated from 120 transects in forest (10 fortnightly transects for 6 months, i.e., 10 x 2 x 6 =120), 60 transects in cardamom (10 x 1 x 6) and 30 transects (5 x 1 x 6 = 30) in coffee habitats, sampled only during the wet season. We determined abundance per transect (individuals/100 m^2) and calculated the average density among transect samples per habitat type (Sluys et al. 2001). The number of frogs sighted per transect sample was considered the encounter rate. Encounter rates of Bicolor Frogs were compared with the daily rainfall, temperature, and humidity in the forest habitat measured prior to initiating the sampling (N = 58).

Four habitat variables (canopy cover, understory cover, litter thickness, and occurrence of water bodies with muddy bottoms and 10 m in diameter) were classified per transect and measured once during the wet season. These variables were assigned scores 1–3 to represent a complete (1), intermediate (2) and low (3) status for the habitat variables following the methods of Fogarty and Vilella (2002). To determine if habitat variables affect frog encounter rate, we tested four habitat features considering the habitat features as dependent variables and frog encounter rate as a fixed factor in multivariate analysis (MANOVA, SPSS 10.0). Similarly, to determine if weather variables affect frog encounter rate we also analyzed three weather parameters (daily atmospheric temperature, relative humidity, and rainfall) as dependent variables and frog encounter rate as a fixed factor in MANOVA. Because the frog encounter rate was not normally distributed, the data were recoded into categories for multivariate analysis. All the tests were conducted at $\alpha = 0.05$.

Preliminary analysis indicated that *Clinotarsus curtipes* was detected on the ground only during the wet season (May to October) and was not sighted during the post monsoon and summer months (Fig. 1). The post monsoon and dry season sampling resulted in very few observations (N = 2) and therefore were not considered for abundance estimations. Transects in forest yielded an average frog abundance of 16.66 / 100 m^2 ($\pm$ 6.58 SE; range 0.0–40.5; N = 120 transect samples). Their abundances in cardamom (mean = 0.98 ± 0.43 / 100 m^2; range 0.0–3.75; N = 60 transect samples) and coffee (mean = 1.07 ± 0.51 / 100 m^2; range 0.0–2.0; N = 30 transect samples) habitats were very low.

Results of multivariate analysis of encounter rate and environmental variables indicated that only atmospheric relative humidity explained frog encounter rate ($F_{3,3,3} = 4508$, P = 0.007). Among four habitat variables, litter cover ($F_{3,3,3} = 5.741$, P = 0.005, N = 25) and presence of lentic water bodies (F = 8428, P = 0.001, N = 25) explained frog encounter rate (Table 1).

Bicolor Frog abundance varied with habitat studied. Their abun-

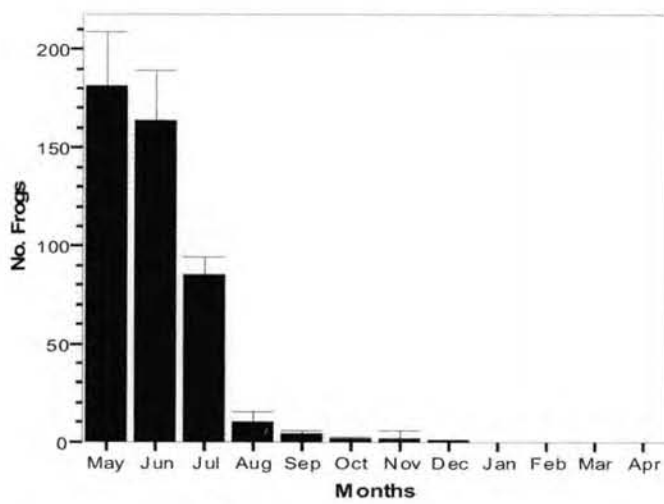

FIG. 1. Seasonal abundance (mean ± SE) of *Clinotarsus curtipes* on the forest floor at Bisale Forest Reserve, Karnataka, Western Ghats, India.

TABLE 1. Results of multivariate analyses of variance (MANOVA) to determine the effect of habitat and environmental parameters on the encounter rate of *Clinotarsus curtipes* from a high elevation site in Bisale Reserve Forest, Karnataka, India.

Dependent Variable	df	F	P
Canopy cover	3	2.130	0.127
Understory cover	3	0.162	0.921
Litter cover	3	5.741	0.005
Water source	3	8.428	0.001
Daily rainfall (24 h)	3	2.273	0.090
Air temperature (°C)	3	2.443	0.074
Relative humidity	3	4.508	0.007

dance was highest in the forest habitat. Their encounter rates were associated with the daily atmospheric relative humidity, litter-cover and presence of mud-bottom water bodies that are larger than or equal to 10 m in diameter. Because the forest habitat of Bisale Forest Reserve is characterized by these features, Bicolor Frogs may be found more abundantly here than other habitats studied. Although they were present in the coffee and cardamom plantations, they were in very low abundance when compared with the forest sites. However, more detailed natural history studies and long-term monitoring would be essential to differentiate varying abundances from a decline or from natural fluctuations (Pechmann et al. 1991). Also, due to our nonrandom site selection, the scope of inference of our study results are limited to the three specific locations surveyed; however, the dramatic differences in densities we observed are relevant to be considered to similar habitats elsewhere. Our results suggest that coffee and cardamom plantations do not provide optimal habitat for Bicolor Frogs.

Similar to Túngara Frogs (*Physalaemus pustulosus*) (Marsh 2001) in secondary tropical moist forest of Panama, abundance of *Clinotarsus curtipes* was related to the presence of a large water body and canopy-covered habitats. Density of *Eleutherodactylus coqui* in Puerto Rico forests was less dependent on plant species richness and composition than vegetation structure (Fogarty and Vilella 2002). Studies have shown that the percent relative humidity alone affects the calling male density of *E. coqui* (Fogarty and Vililla 2001). This might be the case with *C. curtipes* as well. As the cardamom estates are on the hill slopes, the torrential streams are fast-flowing with limited pools. Absence of large mud-bottom, lentic water bodies might be the reason for the low abundance of *C. curtipes* in the cardamom habitat. Similar to Indian torrential frogs, *Micrixalus* (Krishna et al. 2005), *C. curtipes* were more abundant (about 20 times) in forest habitat than the adjacent coffee habitats. Coffee plantations might lack the canopy cover required by these frogs. Reduced canopy cover can increase ambient temperature, reduce humidity, and expose the forest floor (Marsh and Pearman 1997). Synergistic interactions of all such modifications in the coffee habitat might be the reason for their low occupancy in such habitat.

In the Western Ghats, numerous fragmented forests are being converted into plantations. This is a concern for native biota, including frogs such as *C. curtipes*. Although this is not a rare species, being "lower-risk-near-threatened" (Inger and Dutta 1986; Molur and Walker 1998), the maintenance of biodiversity across the forest landscape is an emerging priority to retain forest ecosystem health. At higher elevations, fragmented native forests due to coffee and cardamom plantations are a concern, while at lower elevations, native forests are being converted to monocultures of bamboo and eucalyptus. Furthermore, urbanization (Davidson et al. 2001) and roads may act as barriers for amphibian dispersal (Marsh and Trenham 2001).

Many amphibian populations have been reported to exist as subpopulations across a large geographic area (Lips et al. 2003). Habitat fragmentation may affect metapopulation and genetic structure, in turn affecting a population's ability to respond to the environmental changes (Amphibia Web 2003). This theory has been a basis for conserving species in fragmented habitats (Marsh and Trenham 2001). The synergistic interactions among diverse human impacts on forests such as land use changes, habitat degradation, vegetation removal, litter removal, and removal of non timber forest produce has made the conservation of forests and wildlife a major challenge. The present study provides information on habitat associations of bicolor frogs in the forests of the Western Ghats These data are useful for forest managers while integrating species-specific management strategies into landscape forest management designs (Cross and Petersen 2001).

Acknowledgments.—We are grateful to the Karnataka Forest Department, for the permission and cooperation during fieldwork. We thank Anil Kumar, Sajith and Venkatesh for their assistance in the field data collection. We acknowledge G. Umesh and A. Kumar for allowing us to sample frogs in their cardamom and coffee estates. We are thankful to Deanna H. Olson, Francisco J. Vilella, and an anonymous reviewer for their critical comments that improved the manuscript. We thank Jaime Bosch for statistical suggestions. This work was funded by a small grant by the Wildlife Conservation Society, New York, and by a DAPTF seed grant to the first author.

Compared to literature on other vertebrates, there are few studies on sound production by turtles (Carr 1995). Gans and Maderson (1973) reviewed the literature on reptile sound production and turtles appear to be the least vocal of the living reptiles. However, sounds have been heard and recorded in a number of species. Squealing sounds of young *Platysternon megacephalum* are produced when they are disturbed (Campbell and Evans 1972). The Mexican *Staurotypus* has two very distinct voices (Cope 1865) and two species of *Geochelone* produce sounds in different contexts (Campbell and Evans 1972). Kinosternids, the mud turtles, are also known for sound production (Gans and Maderson 1973).

A number of reports have noted the audible growls of sea turtles, especially *Dermochelys coriacea* (Carr 1995; Lutcavage and Lutz 1997; Mrosovsky 1972). The purpose of our study was to record, characterize and quantify the sounds emitted by nesting Leatherback Sea Turtles. We looked for changes in the sounds that related to the behavioral sequence in female nesting and we tested for correlations between sound parameters (e.g., frequency) and female size. While the sounds produced by nesting leatherbacks appear to be connected with respiration, their potential role in communication, if any, is not understood.

Materials and Methods.—We recorded the sounds of nesting Leatherback Sea Turtles in June 1999 on two beaches of Culebra, a small island off the northeast coast of Puerto Rico. The beaches where the recording took place, Playas Brava and Resaca, are heavily utilized by leatherbacks during the nesting season.

To record the turtles' sounds, we used a Marantz® PMD-222 portable cassette recorder, a Sennheiser® ME66/K6 directional microphone covered with a Sennheiser® MZW 66 foam windscreen to reduce wind noise. The frequency response of the system was ± 3 decibels (dB) from 40 Hertz (Hz) to 12.5 kHz. Recordings were made on one side of the cassette only. The recording system was calibrated by recording a 400 Hz tone prior to and after recording. The calibration signal did not differ by more than 10 Hz or 1 dB re 20 microPascals (uPa) over the entire recording period.

We recorded females during various stages of nesting (egg laying, covering, and camouflaging) by holding the Sennheiser microphone ca. 30 cm from the turtle's mouth. Size (carapace length and width), tag identification numbers (metal clips and PIT microchips), and the number of eggs laid for each recorded female were also noted.

Six hours of tape were recorded from eight female leatherback turtles during various stages of nesting. Of these eight females, two (FAAV and F390) were recorded during the entire nesting process from egg laying through the camouflaging of the nest.

Three other females (F347, F372, F147) were recorded only during covering and camouflaging. The rest of the females (F303, F360, F050) were recorded only during the camouflaging stage.

For each female, we digitized eight minutes of recording during each nesting behavior using a 16-bit analog-to-digital converter at a sampling frequency of 8000 Hz. Measurements were made using CoolEdit '96 program (Syntrillium Software Corp.). All time measurements were made to the nearest 1 ms. The rates of sound production were determined for each of three sound categories (see Results) during each nesting behavior. To ensure consistency across females, the first thirty-five sounds during covering behavior and the last thirty-five during camouflaging behavior were used for analysis (duration, rates and spectral content). The peak frequency of 10 exhales for each female ($N = 8$) were averaged and regressed against female size (carapace length, cm). Because the air passages of a turtle might resemble a resonating closed pipe, we compared our measured relationship to that predicted by a closed pipe using the following formula (Rossing 1990):

$$F_1 = V / 4L$$

where F_1 = fundamental resonant frequency, V = velocity of sound, and L = length of the closed pipe. Note that if length (L) doubles, frequency would be halved.

Results.—Fig. 1 is the sonogram of a recording from one female during camouflaging. Based on audible and quantifiable differences, we distinguished three categories of sound generated by nesting females: exhale/inhale, gular pumps, and grunts. Exhale/inhale was the longest of the sounds produced, lasting on average about 800 ms. Pumps and grunts where significantly shorter at approximately 200 ms and 400 ms, respectively (Table 1). Only five females produced grunts, which were more variable in duration and recorded only during camouflaging behavior. The duration of the exhale/inhale sounds increased significantly between covering and camouflaging the nest (t-test, $t = 3.14$, $P < 0.03$), whereas the duration of gular pumps did not change (Table 1). Although the duration of the exhale/inhale combination increased from covering to camouflaging, the rate at which they were produced remained constant at 4–5 per minute. The duration of pumps did not differ between covering and camouflaging (Table 1), but the rates at which they were produced more than doubled from about 7 per minute during covering to about 17 per minute during camouflaging (Table 2).

TABLE 1. Average duration (SD) of three categories of sound emitted by nesting Leatherback Sea Turtles during two nesting behaviors, covering and camouflaging (averaged across females $N = 5$). Means of each female are based on 35 recordings of each sound during each nesting behavior.

Sound	Duration (ms)		
	Covering	Camouflaging	Overall
Exhale/Inhale[a]	702 (56)	893 (23)	812 (36)
Pumps	214 (26)	209 (7)	209 (9)
Grunts[b]			388 (100)

[a]Significant difference in duration of exhale/inhale during covering and camouflaging ($t = 3.14$, $P < 0.03$).
[b]Based on only 13 sounds from 5 females.

All of the sounds produced by nesting females were broadband, having some energy across the entire 4 kHz range of the analysis. However, there were certain peaks in the spectrum for each of the sounds emitted. Exhale/ Inhale commonly had a spectral peak near 400 Hz and second band around 1200 Hz (Fig. 1). In the exhale portion of the exhale/inhale combination, the peak frequency increases slightly throughout the duration of the sound. The grunts also contained frequencies with peaks that were higher (2000 Hz and up) than exhale/inhale. Pumps did not contain the low frequency peaks (300–500 Hz) common to exhale/ inhale or grunts.

For the two females that we were able to record during all phases of nesting, the number (and rate) of sounds produced increased from egg laying to covering and camouflaging (Fig. 2). Grunts were only produced during camouflaging. One of the females (FAAV) produced pumps only while she camouflaged her nest. The other female (F390) produced pumps during each nesting stage and the number of pumps increased from < 1 per minute while she

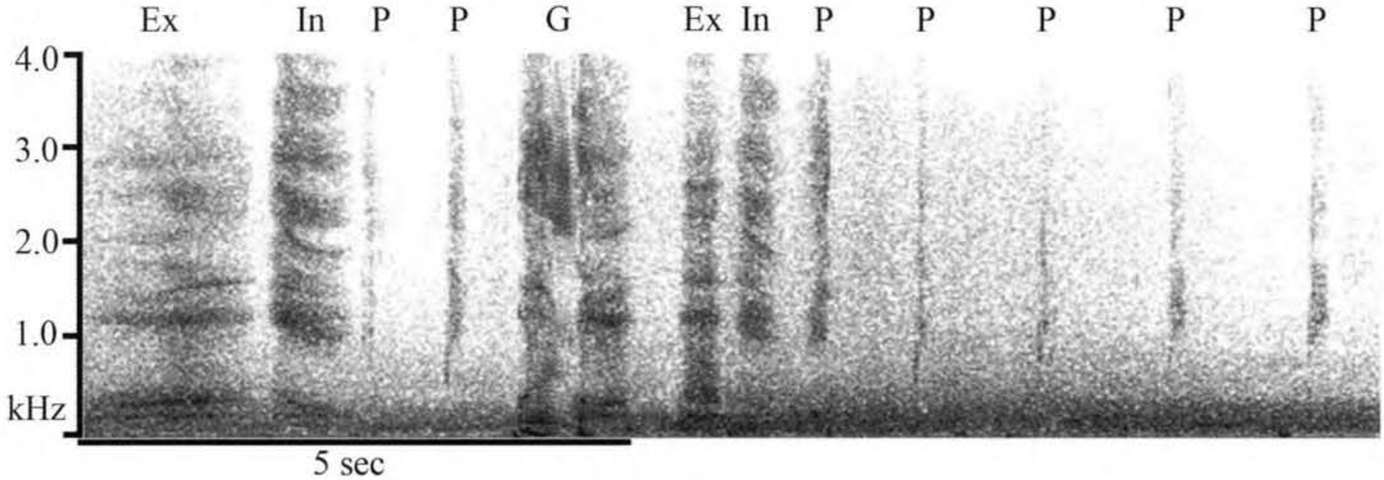

FIG. 1. Sonogram of a recording of one female Leatherback Sea Turtle while she camouflaged her nest site. The gray band extending across the bottom of the sonogram is background noise from the waves breaking on the shore. The darker columns are sounds produced by the female and above each sound its category is indicated (Ex In: exhale/inhale, G: grunt, P: gular pump).

TABLE 2. Mean rate (SD) of sound production of nesting Leatherback Sea Turtles. Averages are based on rates during 8 minutes of recording from each female (N = 5).

Sound	Rate (min^{-1})	
	Covering	Camouflaging
Exhale/Inhale	4.7 (0.7)	4.5 (1.0)
Pumps[a]	7.3 (7.3)	17.2 (6.1)
Grunts	0	0.9 (0.7)

[a]Significant difference in rate of gular pumping during covering and camouflaging ($t = 4.17$, $P < 0.02$).

laid eggs to 10 per minute and 22 per minute while she covered and camouflaged the nest, respectively. Both females increased the rate of Exhale/Inhale during each stage of nesting (Fig. 2).

The peak frequencies of the exhale/ inhale significantly decreased with female size (Fig. 3). We assumed that the air passages would scale linearly with carapace length, our measure of female size. If so, then the resonant frequency of the closed pipe (air passages) should change by a ratio of 0.841 (the ratio of carapace lengths of the largest female to the smallest 138 cm/164 cm) between the smallest and largest females in our sample. Thus, the predicted slope of the relationship is –2.55 Hz / cm (dotted line Fig. 3) and is similar to the slope of the best-fit line, –2.08 Hz/cm (solid line Fig. 3). Using a resonant frequency of 400 Hz, the formula for the closed pipe predicts a length of 21 cm for the distance between the trachea and the open mouth.

Discussion.—Sounds made by animals can be either incidental or communicative. Incidental sounds are by-products of the normal activity of the animal, such as grinding of the shell or closing of the jaws. Communication involves an acoustic signal used by one animal (the sender) to modify the behavior of another animal (the receiver, see Bradbury and Verhencamp 1998).

If the sounds produced by nesting Leatherback Sea Turtles were communicative, they should fall in the audible range for the species. Patterson (1966) used behavioral conditioning to measure audibility in *Trachemys scripta* and found they were most sensitive to frequencies between 200 and 600 Hz. More recently, Bartol et al. (1999) measured the auditory evoked potentials in Loggerhead Sea Turtles to broadcasts of broadband clicks and tone bursts. The sea turtles were most sensitive to frequencies of 250 and 500 Hz with a decreased sensitivity (10–15 dB) to 750 and 1000 Hz. Currently, no data exists on the hearing sensitivity of leatherbacks. However, peak frequencies of the sounds we recorded for leatherbacks were between 300 and 500 Hz (Fig. 3) and are consistent with the low-frequency hearing range found in other turtle species.

During sound production, the leatherback female extends her neck and tilts the head back, towards the carapace, a posture that suggests that she might be broadcasting. This position could also increase airflow into and out of the lungs. The origin of leatherback sounds is the respiratory system and involves movement of air into and out of lungs. For leatherbacks, the increased rate of exhale/inhale, pumps and grunts from egg laying to camouflaging (Fig. 2) presumably relate to increased oxygen demands. Paladino et al. (1990) showed that the metabolic rates of leatherbacks engaged in covering and camouflaging were 0.222 liters O_2/ kg h. In comparison, the metabolic rates for unrestrained leatherbacks during egg laying is only 0.015 liters O_2/ kg h (Lutcavage et al. 1990), nearly a 15-fold difference (Lutcavage and Lutz 1997).

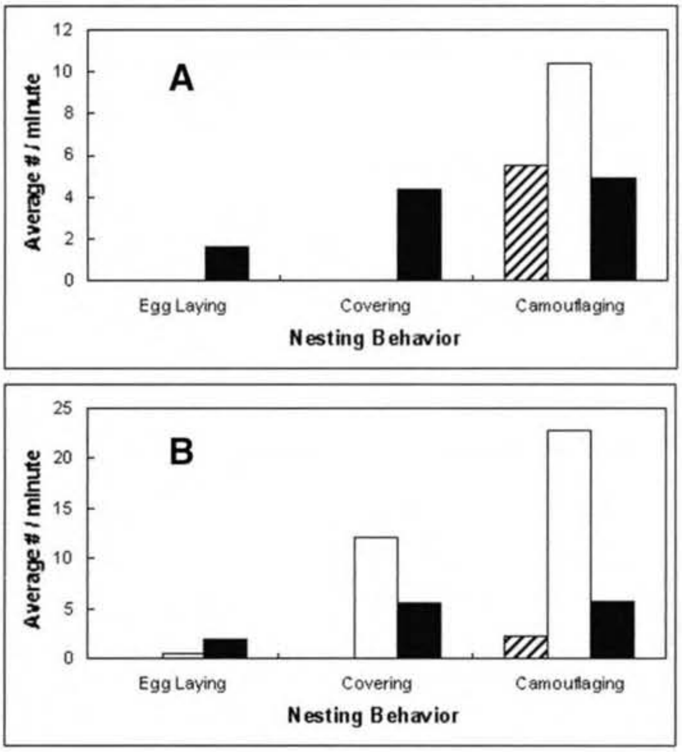

FIG. 2. Rate of grunts (hatched bars), pumps (white bars) and exhale/ inhale (black bars) recorded for two female Leatherback Sea Turtles, (A) FAAV and (B) F390, during three nesting stages. Rates are the average number of each sound type produced during N = 8, one-minute recordings. Both females increased the number of each category of sound as nesting progressed from laying eggs to camouflaging.

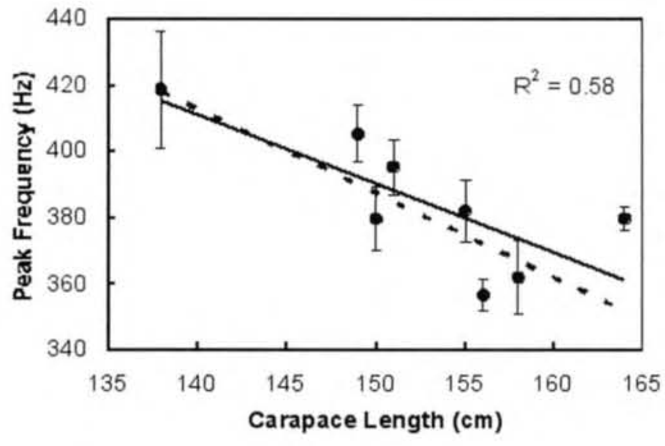

FIG. 3. Relationship between carapace length of nesting Leatherback Sea Turtles and the peak frequency of (exhale/inhale) sounds they emitted. Points are the mean peak frequency (± SE) for each female based on 10 sounds each. The solid line is the best-fit regression for the means ($y = -2.08 + 702$, $P < 0.03$) and the dotted line is the predicted relationship if the air passages of the turtles act as a resonating closed pipe.

Camouflaging a nest is vigorous activity involving active movement of all four flippers to distribute sand. Increased oxygen demand should require significantly longer exhale/inhale and/or an increase in the number of pumps from covering to camouflaging. In the Green Turtle *(Chelonia mydas)* respiratory mechanics involves compression by the body wall and extremities causing extrapulmonary pressure to be slightly positive. Expiration occurs, causing the glottis to open, air to be forcefully expelled, and extrapulmonary pressure to become negative. Filling of the lungs is accomplished by an elastic rebound of the body wall and extremities (Tenney et al. 1974).

Gular pumps may also play a role in respiration by female sea turtles. Tenney et al. (1974) describe them as small expiratory leaks in the green turtle. In reptiles, the gular organ is homologous with the larynx (Blumberg and Alberts 1997), which has muscles controlling the constriction or adduction of membranes that open or close the respiratory airway. Monitor lizards use the hypobranchial apparatus to expand the gular cavity to create positive pressure gular pumps to assist lung ventilation (Owerkowicz et al. 1999).

The sounds produced by nesting Leatherback Sea Turtles are quite loud and impressive. If these sounds are incidental by-products of respiration, selection should act to minimize the number or intensity of sounds produced during egg laying because they might attract predators. If so, we expect females to time their sound emissions with waves breaking on shore so that their sounds would be masked by the environmental noise.

Acknowledgments.—We thank R. Soler, N. Jimenez, and the U.S. Fish and Wildlife Service of Culebra, Puerto Rico for allowing us to conduct the research with these turtles. Research was conducted under permits issued to R. Soler and N. Jimenez.

The American Crocodile (*Crocodylus acutus*) is one of the most widely distributed crocodilian species in Latin America, ranging from the United States to northern South America, including the Caribbean (Ross 1998). However, *C. acutus* populations have declined throughout much of its range because of past overexploitation, continued illegal hunting, and habitat destruction (Ross 1998; Thorbjarnarson 1989). As a result, the species is considered vulnerable by the International Union for the Conservation of Nature and Natural Resources (IUCN), listed on Appendix I of the Convention on Trade in Endangered Species of Wild Flora and Fauna (CITES) (Ross 1998). Furthermore, this species is listed as subjected to Special Protection in the Endangered Species list of the Norma Oficial- Mexicana (NOM-059-ECOL-2000), the Mexican law for the protected species and subspecies of flora and fauna (Diario Oficial de la Federación 2000).

In the past, trade in crocodile skins was a relatively important issue in Mexico, principally in coastal states of Campeche, Colima, Chiapas, Jalisco, Nayarit, Guerrero, Oaxaca, Quintana Roo, Sinaloa, Tabasco, Tamaulipas, Veracruz, and Yucatán (INE 1999). However, this activity declined because of the ban on hunting of wild populations as a result of the lack of management, enforcement of hunting regulations, and overexploitation. In 1970, the Federal Government of Mexico declared the total and permanent protection

of the three species of crocodilians that occur in its territory, *Crocodylus acutus*, *C. moreletii*, and *Caiman crocodilus fuscus* (INE 1999), and legal commerce of skins was suspended. Since then, various studies and distinct conservation programs have been developed in Mexico concerning the status of wild populations, reproduction, population genetics, interaction with humans, and management proposals (Velasco and De Sola 2000).

However, geographically the studies are not well distributed, and surprisingly little is known concerning the abundance and distribution of *C. acutus* along the coast of Quintana Roo. The few studies carried out in this rapidly developing state show a low number of individuals and a slow recovery throughout its former range (Cedeño-Vázquez 2002; Domínguez-Laso 2002). The status, dynamics, and behavior of the population of *C. acutus* at Banco Chinchorro Biosphere Reserve (Fig. 1) are poorly known (Carballar 2001). Such information is essential for the development of appropriate conservation strategies. The objectives of this study were 1) to obtain baseline data to evaluate the status of the *C. acutus* population in Banco Chinchorro Biosphere Reserve, and 2) to suggest conservation actions based on these findings.

Study Area.—The reserve is situated east of the Quintana Roo coast, between the fishing villages of Río Indio and Río Huach (Fig. 1). It is in the open sea 31 km from the village Mahahual, which is the nearest continental point, and separated from the coast by a 1000-m deep channel (UNEP/IUCN 1988). The reserve measures 144,360 ha, which include reef formations, reef lagoons, four cays, and adjacent oceanic waters. It is a reef coral complex and is one of the largest structures of this kind in the Caribbean (Jordán and Martin 1987) and the most important in Mexico. The reef has an irregular elliptic form of 43 km long and 18.0 km wide.

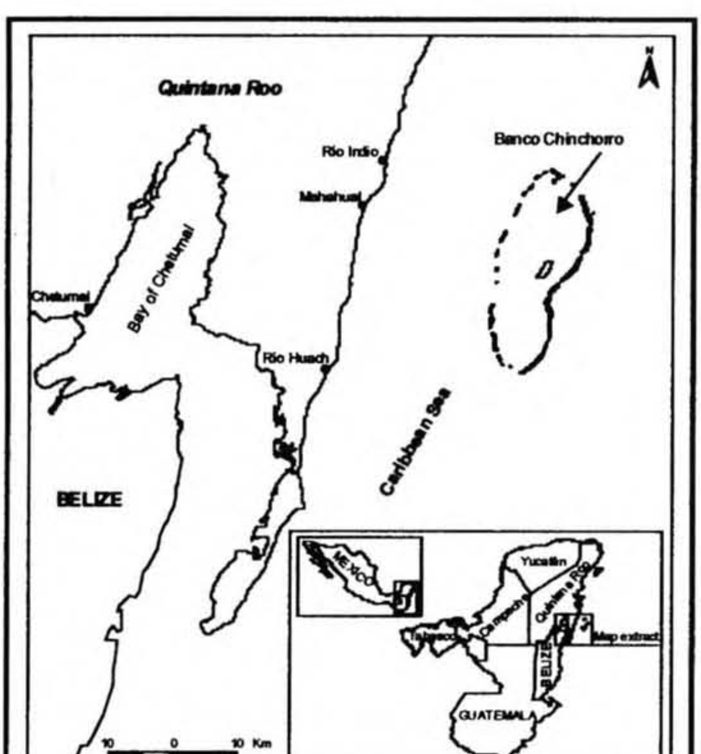

FIG 1. Location of Banco Chinchorro Biosphere Reserve.

The total perimeter of the barrier reef is 115 km (Jordán and Martin 1987). The 53,379-ha reef lagoon is variable in depth, with a decrease in the north–south direction. Four cays occur in a lagoon that covers 582 ha or 0.40% of the total reserve surface. Of this area, 435 ha are terrestrial habitats and 147 ha are interior lagoons. In the extreme north of the reserve is Cayo Norte, with two cays and a total area of 40 ha. Cayo Centro (Figs. 1, 2), localized in the center of the system, is the largest cay covering 541 ha. The fourth cay, localized in the extreme south is the 0.4-ha Cayo Lobos.

The terrestrial vegetation of Banco Chinchorro is comprised of halophytic vegetation or coastal dune vegetation (five different associations), and mangrove: *Rhizophora mangle*, *Avicennia germinans*, *Conocarpus erectus*, and *Laguncularia racemosa* (Cabrera 1998). The shoreline vegetation of the cay was dominated by red mangrove. Three small beaches were found along the shoreline, all associated with fishing camps. There are also fishing huts on pilings in open water in the southeast part.

Methods.—Potential habitat of crocodiles was identified on maps of Banco Chinchorro and by interviewing local fishermen. Three set of spotlight surveys were conducted between June and August 2003 in Cayo Centro. Daylight reconnaissance and nocturnal surveys were conducted using a 4.27-m aluminium boat powered by a 15-hp outboard engine or by paddling along the shoreline and spotting crocodile eyeshines using handheld spotlights (100 and 400 CP) and 4.5-V headlights. A team of two observers, one data recorder, and a boat driver conducted the surveys. Ten different routes were surveyed during the study (Fig. 2). Three different groups of survey routes were described during the study.

The Chandés Lagoon was divided into five routes for survey purposes (Lighthouse Lagoon, Edifice Lagoon, Lagoon A, Lagoon B, and Lagoon C), but all present the same habitat type. The main characteristic of this habitat is its heterogeneity: red and black mangroves constitute many patches in the lagoon, and *Batis maritima* forms carpets of vegetation (30 cm high) on the lagoon shoreline—where the soil is solid (on the east coast) or in 20–cm deep water places where it is usually associated with cut off branches or dead branches and muddy soil. The lagoon is relatively protected against wind and wave action.

Rabios Lagoon, Rabios 2 Lagoon, Perla Lagoon, and Small Lagoon present a habitat characterized by red or black mangrove along the shoreline. These lagoons are linked directly to the sea by openings in the mangroves and are more subject to wave action. The water is also deeper.

Spotlight counts were done on established survey routes to estimate the abundance of crocodiles at each location by recording encounter rate (crocodiles/km) (King et al. 1994). This technique has been used to determine a relative index of the population, because not all the crocodiles present are observed during a survey (Bayliss 1987; King et al. 1990). To maintain similar conditions and to ensure that it was dark enough to detect eyeshine, surveys were conducted at night and began ca. 20–30 min after sunset (Messel et al. 1981). Surveys were not conducted under rough water conditions or during rain, which substantially limit visibility and produce low counts (Woodward and Marion 1978).

For each crocodile sighted, we recorded location with a Global Positioning System (GPS), water salinity (measured with an optical refractometer on scale of 0–100 ppt), habitat type, shoreline vegetation, water depth, and air and water temperatures. Crocodiles

sighted were approached as closely as possible to estimate total length (TL), which was eventually used to determine population structure by size class. We used the following classes, which are those suggested by Platt and Thorbjarnarson (2000) for the species: hatchlings (TL < 30 cm), yearlings (TL = 30.1–60 cm), juveniles (TL = 60.1–120 cm), subadults (TL = 120.1–180 cm), and adults (TL > 180 cm). When TL could not be determined, crocodiles were classified as "eyeshine only." Use of the same observers and equipment reduced observer bias and equipment-related variation.

Encounter rates and abundance were calibrated where data from more than one survey were acquired, according to the method proposed by Messel et al. (1981). Estimations for each size class on each location or survey route were also calibrated (Messel et al. 1981). The coordinates and the time of the beginning and the ending of each survey were documented with a handheld GPS. Survey routes were calculated as shoreline distance along small bays and lagoons (King et al. 1990). Crocodile abundance index was calculated through the encounter rate as the number of crocodiles per kilometer of survey route. A chi-square analysis was used to compare size-class distributions within each site against a null model of equal distribution (Zar 1999).

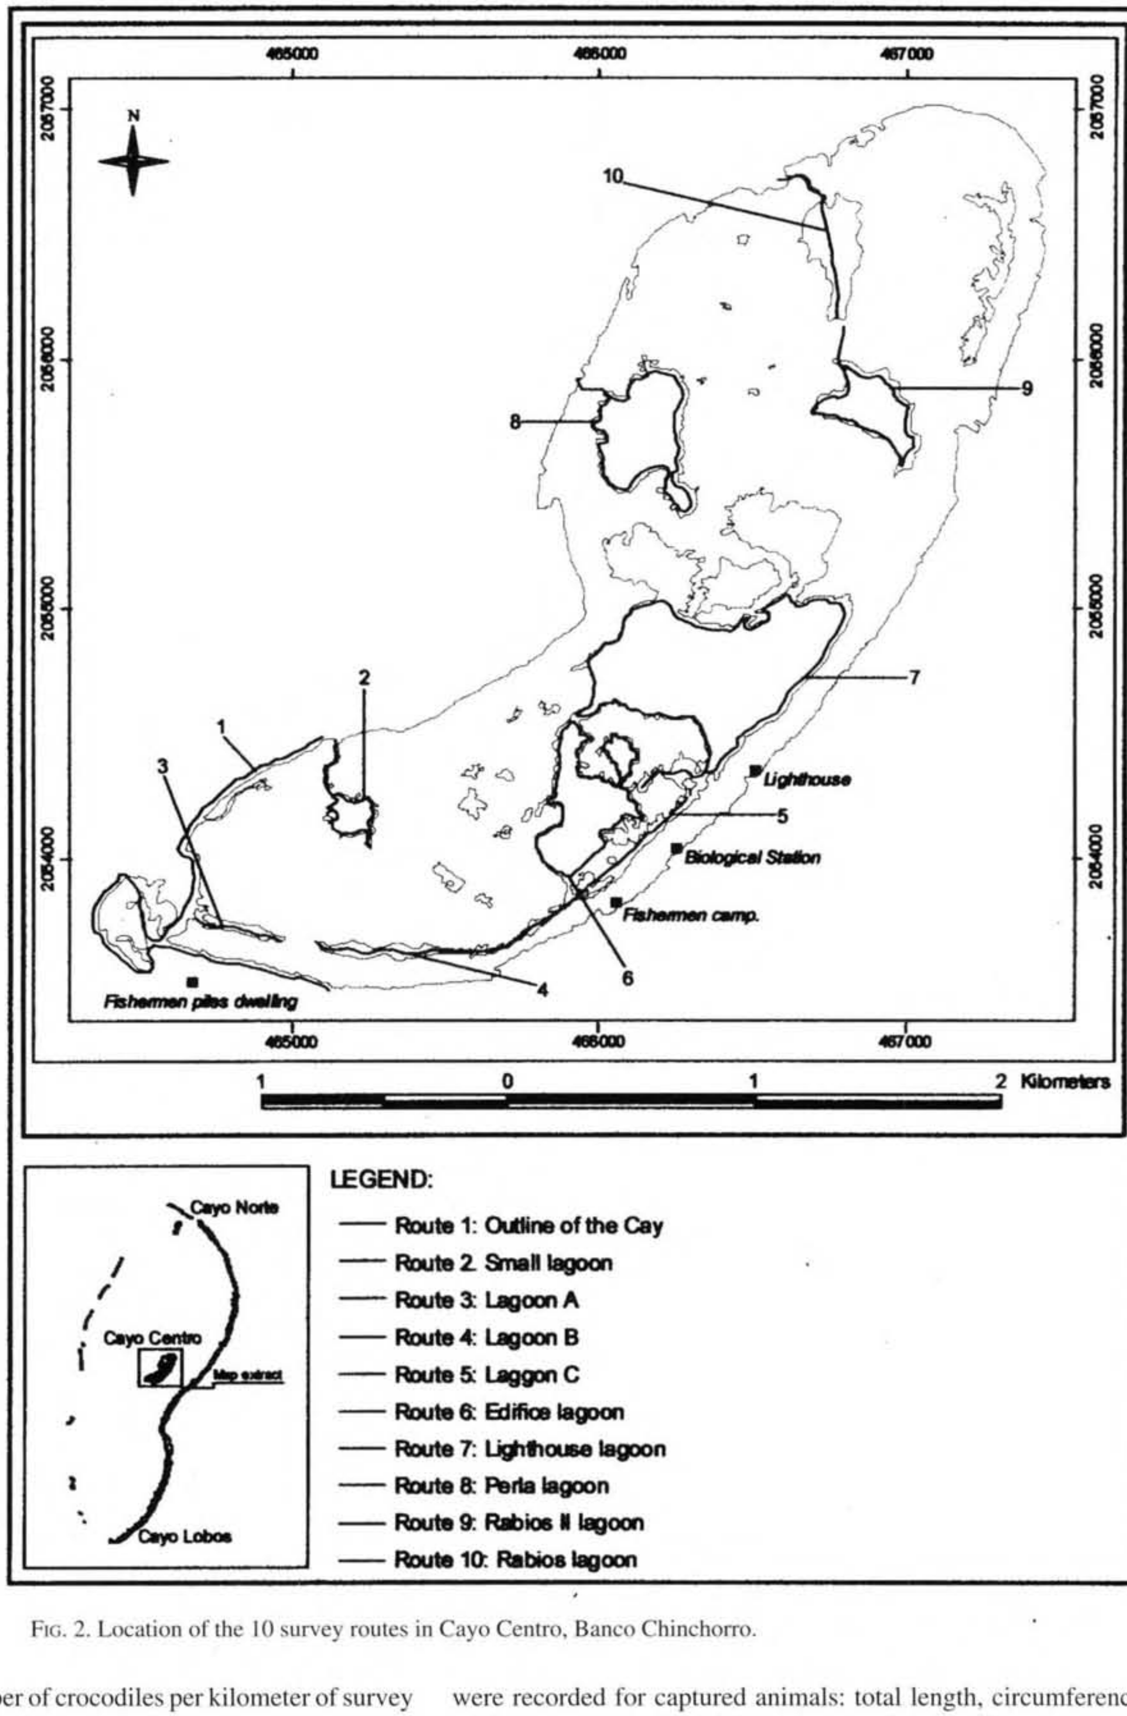

FIG. 2. Location of the 10 survey routes in Cayo Centro, Banco Chinchorro.

Efforts were made during spotlight surveys to capture animals by hand or with a self-locking wire noose. The following data were recorded for captured animals: total length, circumference of the base of the tail (TC), snout–vent length (SVL), and head length (HL), measured with a plastic ruler tape or a plastic caliper to the nearest 0.1 cm. Captured crocodiles were sexed by cloacal examination (Brazaitis 1968; Magnusson 1982). Observed sex ratios by size class and total were tested against a null hypothesis

of 1:1 sex ratio using chi-square analyses with the Bonferroni correction for multiple comparisons (Zar 1999).

Captured individuals were marked by attaching numbered tags and by removing tail scales in a coded pattern (Platt and Thorbjarnarson 1997).

Results and Discussion.—Only two species of crocodiles are present in the coastal areas of the Yucatan Peninsula: *Crocodylus acutus* and *C. moreletii*, and frequently they are sympatric along the mainland coast. Many characters can be used to distinguish the two species: color, snout formation, preorbital ridge, premaxillary suture, scutellation (Platt 1996). Contrary to the species list of the reserve (INE 2000), but in agreement with crocodile specialists, all individuals captured and observed during this study were *C. acutus*, and no *C. moreletii* were observed. In effect, *C. moreletii* is primarily a freshwater species, occurring in brackish water, whereas *C. acutus* is associated with brackish and saline habitats (Cedeño-Vázquez 2002; Platt 1996; Thorbjarnarson 1989). Our data support these findings and suggest that with a mean salinity of 52.9 ppt (minimum 30 ppt, maximum 61 ppt), *C. moreletii* is unable to live in the cay.

Furthermore, high salinity and lack of fresh water presents a problem in osmoregulation for hatchlings crocodiles (Platt and Thorbjarnarson 2000; Thorbjarnarson 1989). The principal behavioral mechanism used by crocodiles to maintain water balance is probably drinking brackish water made available ephemerally by rain (Mazzotti 1983). We hypothesize that growth and survival of hatchling crocodiles is limited by rainfall on offshore islands.

A total of 147 *C. acutus* were observed during daylight reconnaissance and spotlight surveys. Of these, 34 (23.1%) were classified "eyeshine only," 53 (36.1%) were captured, and 60 (40.8%) were approached closely enough to estimate size. The population size class structure (Fig. 3) was estimated from crocodiles captured or approached closely enough to estimate total size (N = 113).

We used the size class scheme proposed by Platt and Thorbjarnarson (2000) in neighboring Belize for comparative purposes. They observed that, in Belize, individuals over 4.0 m TL are rare, although *C. acutus* is known to attain maximum total lengths of 6.25–7.0 m elsewhere (Thorbjarnarson 1989). Their observations indicate that in Belize *C. acutus* might attain a smaller body size than reported for other populations. It is unknown whether this is because of genetic or environmental factors, or perhaps a consequence of past overharvest which removed most large adults (Platt and Thorbjarnarson 2000). Our results are consistent with these findings—only 3 (2.7%) crocodiles had a total length > 240 cm. The largest crocodile sighted was an individual encountered in the Chandés Lagoon for which we estimated a total length slightly longer that 3.0 m.

An apparent absence of large specimens indicates that the population might still be in a state of recovery from past poaching in the region (according to local informants there is not evidence of poaching still occurring) or, that crocodiles simply do not grow very large in these offshore habitats as a result of genetic and environmental factors as suggested by Platt and Thorbjarnarson (2000). Another possible explanation could be the limited nesting habitat, since only three small beaches were found along the shoreline (Mazzotti, pers. comm. 2004). Juveniles (N = 30, 26.5%) and subadults (N = 31, 27.4%) were most abundant, followed by adults (N = 23, 20.4%), yearlings (N = 15, 13.3%), and hatchlings (N = 14, 12.4%). The lower number of hatchlings and yearlings in the atoll might reflect sampling bias as they might be concealed within vegetation and escape detection during spotlight surveys (Platt and Thorbjarnarson 2000). Another explanation could be lack of fresh water that may limit the survival of young individuals. Although few potential nesting sites are available on the atoll, reproduction is occurring as indicated by our observations of hatchlings. Few potential predators of nests were observed (crabs were the only potential egg predators we observed), and as the area is a biosphere reserve, habitat is effectively preserved. However, natural disturbances caused by hurricanes are frequent.

A total of 133 *C. acutus* were observed along survey routes. We estimated an overall encounter rate of 6.8 crocodiles/km, but important differences among the three habitat types were detected. We obtained a high density (13.9 crocodiles/km) in the Chandés lagoon compared to 1.3 and 1.1 crocodiles/km, respectively, in the outline of the cay and the other lagoons. These last two values are not very different from the density of 0.94 crocodiles/km encountered by Platt and Thorbjarnarson (2000) in atolls in Belize. Furthermore, Carballar et al. (2001) found an encounter rate of 1.8 crocodiles/km in the lagoons and 0.37 crocodiles/km outside the cay. Our results, with 8.4 and 1.3 crocodiles/km in the same sites, are much higher. These differences might indicate an increase in the number of crocodiles over the past two years in the interior lagoons or, more likely be the result of differences between survey methods and perhaps choice of survey sites. It seems that Carballar et al. (2001) did not survey lagoons A, B, and C—locations where we encountered the most individuals.

Notably, the size-class distribution of crocodiles is significantly different in each habitat ($p < 0.05$; df = 2). Although all classes were represented in the Chandés lagoon, we encountered only two subadults in other interior lagoons, whereas eight adults, one yearling, one juvenile, and one subadult were found on the outside of the cay. Few individuals inhabit the outline of the cay and lagoons other than Chandés, and those we encountered were primarily subadults or adults, which are more able to tolerate wave action, deep water, and difficult accessibility to the shore. In contrast, the Chandés lagoon, with its heterogeneous habitats and relative protection from wind and wave action, is ideal for all age classes.

Among the Crocodylidae, both male and female-biased

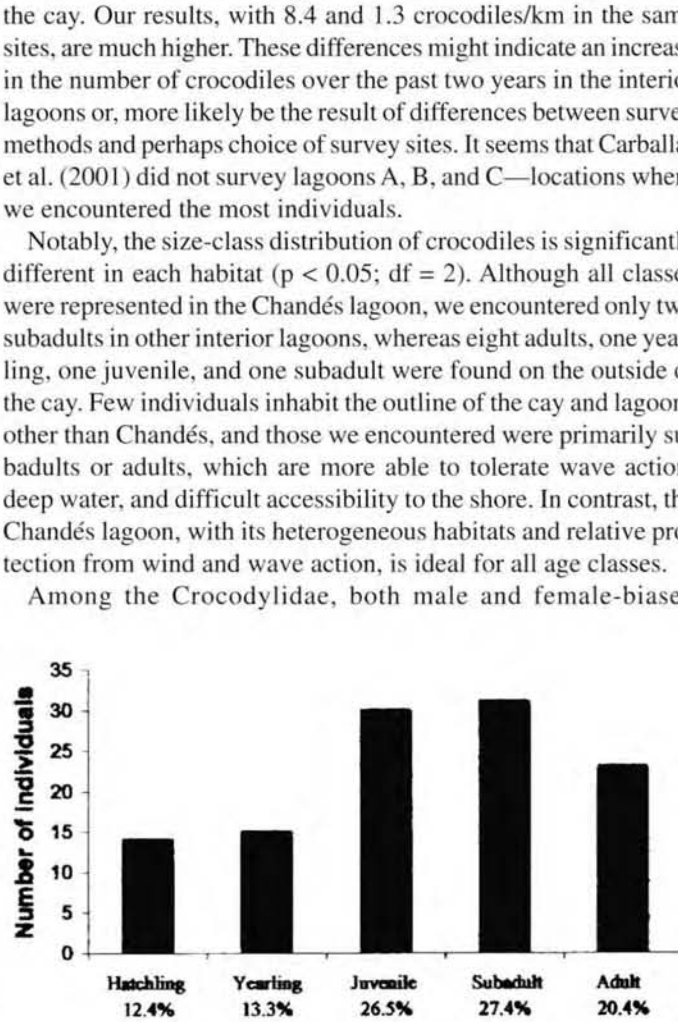

FIG. 3. Population structure by size class of *Crocodylus acutus* of Cayo Centro (Banco Chinchorro).

TABLE 1. Comparison of the sex ratio of American Crocodiles captured in Cayo Centro (B. Chinchorro).

Age class	Males	Females	Sex ratio	χ^2
Yearling	6	0	6:0	6.0 NS
Juvenile	12	2	6:1	7.1*
Subadult	8	1	8:1	14.4*
Adult	8	2	4:1	13.8*
Total	34	5	6.8:1	21.6*

NS = not significant.
* = significant at $p \leq 0.05$.

population sex ratios are known, including at the intraspecific level (Carrion et al. 2000; Thorbjarnarson 1997). Although male-biased populations have been reported (Thorbjarnarson 1988, 1989), sex ratios not significantly different from 1:1 are the most common for *C. acutus* populations (Brandt et al. 1995; Cedeño-Vázquez 2002; Cherkiss 1999; Gaby et al. 1985; Kushlan and Mazzotti 1989; Moler 1991; Platt and Thorbjarnarson 2000). The population of Banco Chinchorro is thus an exception, as it presents a strongly male-biased sex ratio in all age classes, except for yearlings (Table 1). This class presents a tendency of being male biased too, but the small number of individuals might not be sufficient to detect differences from a 1:1 model. Concerning the hatchlings, we had a sufficient number of individuals, but we were not able to sex them (Allsteadt and Lang 1995; Joanen and Mc Nease 1978).

Conclusions.—The current status of *C. acutus* in Banco Chinchorro Biosphere Reserve seems good. Most crocodile populations are resilient to overexploitation and respond well to protection (Bayliss 1987). However, various studies showed that coastal populations of *C. acutus* remain low in most locations (Cedeño-Vázquez 2002; Mazzotti 1999; Platt and Thorbjarnarson 2000). In Banco Chinchorro, the population was subjected to hunting in the past, with a report of 21 animals killed in one night by one person (M. Colli, pers. comm. to PC), so we can reasonably estimate that the population was low when the hunting ban was established. The hunting ban, which was respected in the early 1980's, and the classification of Banco Chinchorro as a biosphere reserve in 1997, allowed the crocodile population to begin recovery. Commercial fishing activities are presently not occurring near the cay, so drowning mortality in nets does not represent a threat to crocodiles as it is in Belize (Platt and Thorbjarnarson 2000). The reserve is well protected and we did not detect hunting of crocodiles, and fishermen, who are the only inhabitants of the cay, coexist with the crocodiles and take care of them. Although we observed garbage on potential nesting sites, destruction of habitat or tourism-related development is non-existent. Banco Chinchorro Biosphere Reserve offers good conditions for long term survival of the crocodile population. The fact that the site is so far off the mainland coast means living conditions for crocodiles are unusual (high salinity, apparently closed population), and we can infer that specific adaptations have been developed. Finally, although the population seems to be undergoing a recovery, management actions and a population monitoring program are necessary. The monitoring program will be important to determinate population conservation strategies and should be based on nest counts, together with spotlight and capture surveys.

Management Implications.—Although fishermen live in harmony with crocodiles, we suggest environmental education programs directed to fishermen and children in schools of coastal villages of Quintana Roo. We think that it is important that they understand that we should protect crocodiles and avoid contact. Children will be the future actors of this region, and it is necessary to inform them of the importance of environmental protection, especially of large predators which are often eliminated when they live near humans. Several studies could be targeted on the American Crocodile population of Banco Chinchorro. These studies could provide particular information on the adaptation of the species, and could serve to improve the conservation programs. We suggest studies focused on the relation of young *C. acutus* to salinity levels, and on the location of actual and potential nesting sites. These studies appear very important to us because the protection of young individuals and the preservation of nesting and nursery habitat are crucial for long-term population viability, and the most important element of any conservation plan (Platt and Thorbjarnarson, 2000). We suggest also that a more precise study is necessary to confirm and examine the causal factors of the apparently male-biased sex ratio of the population.

Acknowledgments.—We thank El Colegio de la Frontera Sur and Banco Chinchorro Biosphere Reserve, especially Tomás Camarena and Bárbara Reveles, for allowing the fulfillment and development of this work, and for their hospitality. We are particularly grateful to Mauro Collí (Chandés), Roberto Rojo (Chibebo), Alejandro Vega, Alejandro Franco, Gabriela García, Antalia González, Victor Hugo Luja, Derek Hogan, and Camilo Mora, for help and support in the field, but also for their friendship. We thank Enrique Escobedo and René Calderón for lending material. We thank Holger Weissenberger, working in the Statistical and Geographical Information Analyst Laboratory (LAIGE) of ECOSUR, for his help in the elaboration of the maps.

Predation of Juvenile and Adult Anurans by Invertebrates: Current Knowledge and Perspectives

LUÍS FELIPE TOLEDO
Departamento de Zoologia, Instituto de Biociências
Universidade Estadual Paulista, Rio Claro, São Paulo
Caixa Postal 199, CEP 13506-970, Brazil
e-mail: toledolf2@yahoo.com

Anuran amphibians are preyed on by vertebrates, invertebrates, and even carnivorous plants (Duellman and Trueb 1994). Most of these reports on predation are anecdotal (Fitch 1987; Greene 1993) and do not provide data other than a short description of the predatory event (e.g., Boistel and Pauwels 2002; Brandão and Garda 2000; Del-Grande and Moura 1997; Mitchell 1990). The scattered information on the subject makes it difficult to identify patterns. Additionally, McCormick and Polis (1982) pointed out the lack of quantitative data evaluating the impact of arthropod predators upon vertebrates. This is particularly true for predation by invertebrates upon post-metamorphic (generally adult) anurans. For example, reports on this subject usually state that few cases of invertebrate predation upon anurans are recorded (e.g., Bastos et al. 1994; Bernarde et al. 1999; Del-Grande and Moura 1997; Hinshaw and Sullivan 1990; Mitchell 1990), when, in fact, a considerable amount of information is generally available (e.g., McCormick and Polis 1982). Therefore, I review the subject in an attempt to depict our current knowledge, add unpublished data, and provide a background to which new reports may be added.

By reviewing published information on the subject I collected data on a wide range of taxa, i.e., at least 68 post-metamorphic (juvenile to adult) anuran species preyed upon by at least 57 invertebrate species, including arachnids, crabs, leeches, and various insect groups (Tables 1 and 2). Besides the species listed (Table 2), there exists indirect evidence and laboratory studies that add

TABLE 1. Invertebrate predators and number of species reported to prey upon post-metamorphic anuran amphibians.

other potential invertebrate predators to the list, such as spiders (*Oilos antaguensis*, *Stasina portoricensis*, and *Avicularia latea*), amblypygids (*Phrynus longipes*), and forest crabs (*Epilobocera situatifrons*) (Formanowicz et al. 1981; Stewart 1995). Laboratory studies using pipid and hyperoliid frogs report pisaurid spiders as additional potential predators upon previously unreported anuran families (Table 2).

It appears that many anuran species can be preyed upon by invertebrate predators, independent of prey body size/age (see discussion in McCormick and Polis 1982), phylogeny, or recognized presence of an elevated quantity of biologically active skin secretions (Duellman and Trueb 1994) (Table 2). However, the risk of predation by invertebrates seems to be greater in two crucial periods of the anurans life cycle: 1) during the breeding season, when most species enter the water and consequently are in contact with potential aquatic predators (e.g., Bastos et al. 1994; Haddad and Bastos 1997; Toledo 2003); and 2) when the recently-metamorphosed frogs are about to leave or actually leave the water (Fig. 1), thus facing both aquatic and terrestrial invertebrates (e.g., Clerke and Williamson 1992; Hirai and Hidaka 2002; Robertson 1989; Toledo 2003). Almost 90% of the observations that provide descriptions of the frog behavior before the predation were recorded during these two stages.

Predation events occurred both in and out of the water and about 73% of them involved water bugs (approximately 25%) and spiders (approximately 48%) as anuran predators (Fig. 2). This may reflect the high density of these animals in nature (DuBois and Gobin 2001; Formanowicz et al. 1981; McCormick and Polis 1982; and references therein). Additionally, it could indicate that spiders and water bugs may be significant predators of anuran populations (Formanowicz et al. 1981; Toledo 2003), though, few studies have determined actual predation rates on adult anurans (e.g., Haddad and Bastos 1997; Hinshaw and Sullivan 1990).

In reviewing the subject I was able to identify a few cases of incorrect or repeated data. For example, Nauman and Dettlaff (1999) reported "the first published record of a giant water bug preying on an adult frog"; however, at least three reports on giant water bugs preying on adult frogs were already available by that time (Bastos et al. 1994; Haddad and Bastos 1997; Hinshaw and Sullivan 1990). Additionally, both Toledo (2003) and Brasileiro

FIG. 1. Juvenile *Hyla albosignata* being preyed upon by a tarantula on vegetation near a stream in a forested area, Municipality of Pilar do Sul, State of São Paulo, Brazil. Photograph by André Antunes.

TABLE 2. Post-metamorphic (juvenile to adult) anurans (15 families; at least 68 species) reported as prey of invertebrates (22 families; at least 57 species) and the microhabitat where the predation occurred. Anuran specific names follow Frost (2004), and thus some genera and species are updated. Predators' abbreviations are in table 1. An asterisk (*) after the anuran names indicates the recognized presence of a high amount of biologically active skin secretions.

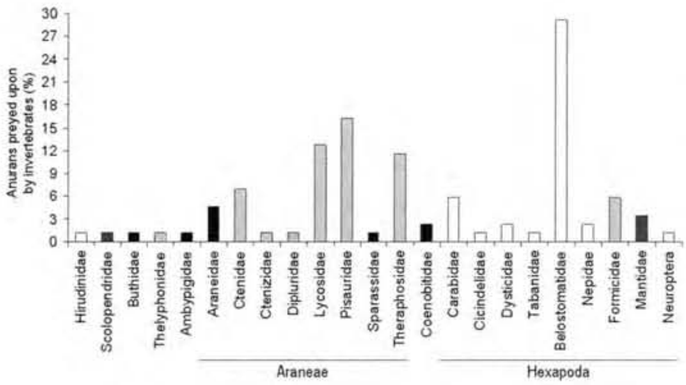

FIG. 2. Percentage of different anuran species that were preyed upon by different invertebrate families based on references listed in Table 2 (N_{total} = 89 accounts). White bars indicate predation events reported to occur in the water; dark bars indicate predation events out of the water; gray bars indicate predation events both in and out of the water; and striped bars represent lack of information on the microhabitat in which the predation occurred.

et al. (2003) provided duplicate reports of the predation of *Physalaemus cuvieri* by the same water bug species (*Belostoma elongatum*) at the same study site. Nevertheless, repeated records may be beneficial as they provide more evidence for an actual predator-prey relationship, and may help determine if any geographic variation occurs in the predator-prey relationship.

Despite the considerable number of reports much more information is likely to appear in the next few years. However, the simple descriptions of a predatory event without providing further details (e.g., microhabitat and prey activity before predation - data that should generally be available to the observers) make future discussions and predictions difficult (see Greene 1993). Therefore, even reports on simple interactions between predator and prey (particularly in the context discussed here) should provide more detailed accounts whenever possible (see complementary discussions in Greene 1986; 1993).

Acknowledgments.—I thank Célio F. B. Haddad, Ivan Sazima, Denis V. Andrade, Anne d'Heursel, Toshiaki Hirai, Ricardo S. Ribeiro, John A. Crawford, Christopher A. Phillips, and an anonymous reviewer for the discussion and comments on earlier drafts of the manuscript; Luís M. Giasson, Toshiaki Hirai, André Antunes, and Jean-Louis Guillaumet for providing unpublished records; Débora Y. F. Campos and Marcelo Menin for helping with references; Biota FAPESP for financial support to the Herpetology lab (grant 01/13341-3); CAPES, Neotropical Grassland Conservancy, and Idea Wild for grants received.

Crocodilian diets can be studied by observing what an animal eats, conducting feeding trials on captive animals, performing biochemical and isotope analysis, or by obtaining samples of the ingested food from the stomachs of wild animals. Stomach contents can be obtained post-mortem from specimens killed for that purpose or collected incidentally from commercial harvests. However, many crocodilian species are threatened or endangered and there are ethical and practical constraints on killing animals for study. Therefore, non-lethal methods have been developed to obtain stomach contents from live crocodilians without causing them harm.

Non-lethal methods used to obtain the stomach contents of crocodilians fall into three categories: invasive scoops that mechanically retrieve material through the esophagus (Taylor et al. 1978), irrigation methods that introduce water and flush material from the stomach (Fitzgerald 1989; Taylor et al. 1978) and combinations of these (Webb et al. 1982). These methods vary in effectiveness at recovering all the stomach contents, ease of application in the field and degree of invasive trauma to the animal. The purpose of this study is to evaluate the hose-Heimlich technique (irrigation method) for accuracy and to check for internal damage on American Alligators (*Alligator mississippiensis*). We also report on the effectiveness of the hose-Heimlich technique used during an alligator diet study, and we investigate alternative water sources for use with this technique.

The hose-Heimlich technique described by Fitzgerald (1989) was used to obtain the stomach contents from live adult American

alligators during a diet study at three lakes in central Florida in 2001–2003 (Rice 2004). Alligators were caught from an airboat between 2200 and 0400 h and tagged, weighed, measured, lavaged, and then released back into the lake. We tested the accuracy and reliability of the hose-Heimlich technique in 2001 on 20 alligators, which were lavaged and then euthanized for collection of tissues for another study. We examined the stomach contents at necropsy to determine the proportion of contents previously recovered. In addition, we checked for any damage to the esophagus or stomach caused by the procedure.

To perform the hose-Heimlich technique, each alligator was strapped to a 245 x 31 cm plywood board and placed at an incline, resting on a wood sawhorse. The jaws were secured opened with a heavy-duty PVC pipe (200 mm length, between 60 and 150 mm diameter) of appropriate size. A soft Teflon hose (5–15 mm diameter) coated with mineral oil was inserted through the esophagus and into the stomach. We previously had established by dissection that the fourth whirl of scutes anterior to the hind legs provided an external marker of the posterior end of the stomach allowing proper placement of the hose. The Teflon hose was connected to a garden hose and, subsequently, a water source. The water source was a domestic water supply, or the lake using an electric bilge pump or a 3.5 hp Briggs and Stratton motor driven pump. All sources delivered water at the rate of approximately 50 L/min.

Each alligator was angled down with its mouth positioned over a 68 L bucket. With the hose in the alligator's stomach and the water running, the animal's abdomen was squeezed in a manner similar to the Heimlich maneuver (Heimlich 1975) resulting in the expulsion of stomach contents and water into the bucket. This lavaging process was repeated until only clear water was entering the bucket. The contents of the bucket were poured through a 0.5 mm mesh nylon strainer and collected in 10% buffered formalin in a 1 L plastic jar labeled with lake, date, and identification numbers on each jar.

The hose-Heimlich technique has been successfully used in several studies to obtain the stomach contents from live crocodilians (Barr 1994, 1997; Fitzgerald 1989). Fitzgerald (1989) tested the technique for effectiveness on Spectacled Caiman (*Caiman crocodilus*) and found that it removed 100% of the caiman's food content. However, Fitzgerald (1989) did find that some caiman retained stones in their stomach. In the 20 alligators that were lavaged and then dissected, we found only one instance where the hose-Heimlich technique was incomplete. During necropsy, we found a large piece of gar (*Lepisosteus* sp.) that had blocked the sphincter and thus prevented the exit of water and stomach contents. Therefore, we characterized an incomplete lavaging process by low water and stomach content output, and by bloating of the stomach area that made it impossible to squeeze.

The technique does sometimes cause minor irritations to the alligator's esophagus and cardiac sphincter; however, most of these irritations were minor (Fitzgerald 1989). We also found some abrasions on the alligator's esophagus and cardiac sphincter, but believe that these were minor and temporary. Animals kept in captivity for periods up to 14 months and those recaptured (two recaptures occurred 63 days after receiving the hose-Heimlich technique) appeared normal (Rice 2004).

During the study of alligator diets in three central Florida lakes (Rice 2004), the technique was applied to 162 adult alligators (182–304 cm total length [TL]) and an incomplete sample (described above) occurred four times. The prey obtained varied in size from invertebrates that weighed < 1 g to fishes weighing over 300 g. The technique also was successful in obtaining non-prey items including vegetation, wood, rocks, toys, fishing lures, and fishing line.

Fitzgerald (1989) identified the need for water under pressure as a disadvantage to the hose-Heimlich technique. However, by using a bilge pump or gas powered motor, we adapted the method for use where a domestic water source was unavailable, and both alternate water sources worked as well as a domestic water source. Barr (1997) also used a portable water pump to flush hundreds of alligator stomachs.

The hose-Heimlich technique proved to be most effective on alligators ≤ 290 cm TL. Two separate attempts to lavage alligators 304 cm TL failed because we were not strong enough to squeeze the alligator's large abdominal area. The largest alligator that was successfully lavaged was 290 cm TL. The largest caiman Fitzgerald (1989) tested the hose-Heimlich technique on was 108 cm snout–vent length (ca. 216 cm TL) and the largest alligator Barr (1997) sampled was 317 cm TL; however, most of Barr's (1997) study animals were < 152 cm TL. When examining the diet of large alligators (i.e., > 290 cm TL), it might be advisable to use an alternate technique.

Acknowledgments.—We thank H. Franklin Percival for support of this project and review of the manuscript. Allan "Woody" Woodward and Dwayne Carbonneau, Florida Fish and Wildlife Conservation Commission, were helpful with assistance in the field. We also thank our field technicians and volunteers who assisted with this project. The St. Johns River Water Management District, Lake County Water Authority, Florida Fish and Wildlife Conservation Commission, Florida Museum of Natural History and the Florida Cooperative Fish and Wildlife Research Unit provided essential funding, facilities, and/or equipment for this project.

Knowledge of animal coloration is of central importance to understanding sexual selection, predator-prey relationships, and thermoregulation (Cloudsley-Thompson 1999; Endler 1990; Norris 1967). However, describing animal color signals is a conceptual and technical challenge. Two sets of methods have been primarily used to meet this challenge: human-based (e.g., Zucker 1988) and spectrophotometric methods (Endler 1990).

Munsell color chips are a human-based method often used to quantify animal colors (e.g., Zucker 1988). This method involves matching by eye samples of printed colors to animal colors. These colors are quantified by assigning them a hue (or dominant wavelength), saturation (or purity of color), and brightness (or total reflectance across a given bandwidth) based on a match to a color chip with those values. However, because such measures are subjective, both intra- and inter-observer repeatabilities of scores are likely to be low. Another difficulty is that low intensities of ambient light can lead to several colors of different hues, saturations, and brightnesses appearing identical to a human observer. The quality of ambient light can also be problematic: in a forest where green light is reflected from trees, a white surface will appear green (Endler 1990). Another limitation of color chips is that they offer discrete choices for continuously varying hue, saturation and brightness. Finally, any human-based method ignores the fact that two colors that appear identical to a human observer might be perceived as different by another animal due to varying retinal sensitivities. Therefore, color methods based solely on human abilities have only limited power to determine the color variation that other animals perceive.

Spectrophotometry (Endler 1990), while much more objective than human based observations, also has limitations. Unlike human-based methods, spectrophotometry can be used to analyze colors well outside the gamut of those perceptible to humans. However, as with color chips, spectrophotometers only take point measurements of reflectance spectra, and thus cannot analyze color patch sizes and color patterns. Additionally, spectrophotometry is logistically difficult and invasive, since it requires capturing an animal and restraining it under a sensor. This drawback may be particularly problematic for lizard color analysis, since some lizards change color rapidly when handled (Norris 1967).

We present a new method for quantifying animal colors and their substrates using digitized photographs. While this method may not capture all the color variation perceived by any given animal, it offers advantages over other methods in that it is objective, allows for analyses of color patterns rather than single points, and allows determination of the size of a color patch. It may also be used to quantify dorsal colors of animals and that of their backgrounds in nature without capture. This method differs from most previous photographic-based methods in that other methods have either used subjective assessments of photographs (West and Packer 2002), or have quantified unstandardized photographs (Haeger 2002). We present data from analyses of color pattern variation in Ornate Tree Lizards (*Urosaurus ornatus*). This study has two objectives: to present a method for color analysis of photographs, and to apply these methods to two specific instances of color analysis in *U. ornatus*. We further suggest photography-based techniques that are not limited by human-visible spectra as measured by typical photographs.

Study Animals.—Ornate Tree Lizards (*U. ornatus*) have been the subject of numerous accounts of how color patterns may be used in conspecific signaling. Hover (1985), as well as Thompson and Moore (1991), described how gular (= throat) color badges may influence dominance relationships. These authors categorized male tree lizards into two groups: lizards with a patch of blue or green surrounded by a ring of yellow or orange were categorized as 'orange-blue' males that assumed a dominant social status. Alternatively, 'orange' males were those that did not have a distinct central patch and were submissive in social interactions (Thompson and Moore 1991). These authors defined an orange-blue male as one that had more than 10% of his total gular patch comprised of the central blue patch, whereas an orange male was one that had less than 10%. These operational definitions apply to most animals in some populations (P. Hamilton, pers. obs.; Thompson and Moore 1991). However, some individuals do not readily fall into either the orange-blue or orange categories. This includes males that have two distinct colors that blend together, rather than forming a distinct central and peripheral color, and males with a yellow central patch with an orange periphery and those with a purplish center and an orange periphery (Fig. 1e).

Tree lizards have been the subject of study for another color-based intraspecific signal, termed dorsal darkening (Zucker 1994). Zucker (1994) found that once a male gained a dominant status, it would exhibit a dark dorsal color, while losers of dominance interactions displayed a lighter color resembling that of females. Dorsal darkness was measured by comparing a lizard's dorsal color to that of a grayscale standard. Subjectivity is a concern here. If the scorer of such colors knows the contest outcome and then scores darkness, such scores may be biased. Furthermore, in order to be blindly scored by naive observers, the lizard must be removed from its social setting, which can cause the dorsal color to change rapidly from handling stress (Norris 1967). Thus, as for gular colors, there is a need for an unbiased, quantitative measure of color for analyses of dorsal darkness that reduces or eliminates the potential effects of handling stress.

Although Ornate Tree Lizards vary extensively in color characteristics, this study is not intended to characterize all, or even most, of the color variation found. Rather, it is an attempt to apply a new technique to specifically describe throat types and dorsal darkness. Thus, we shall only present data that bears on variables

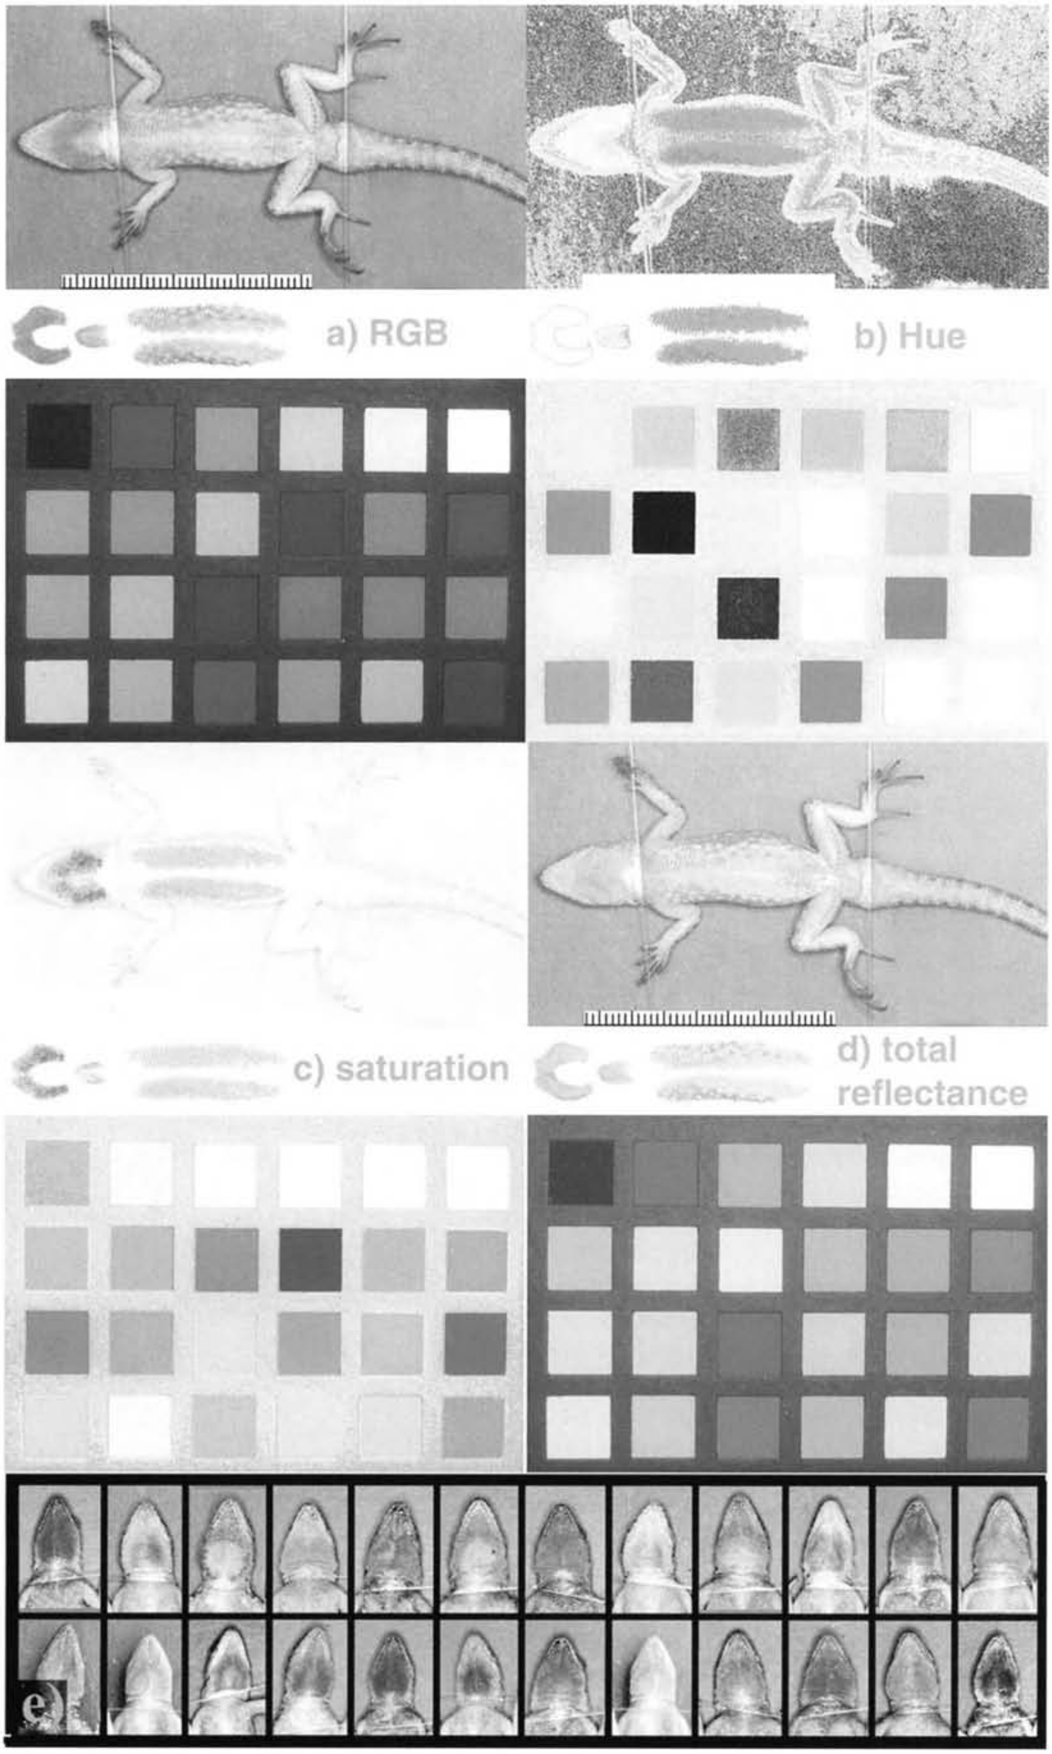

FIG. 1. A digitized image (a) is separated into three digital layers: b) Hue, c) saturation, and d) total reflectance are each represented as optical density. E) A representative sample of throat colors in Ornate Tree Lizards from Sierra Estrella, Arizona, USA.

that have previously been used to describe these traits: hue and size of gular color patches, and reflectance of the dorsum.

Methods and Materials

The lizards used in this experiment were collected from the Estrella Mountain Regional Park in Maricopa Co., south-central Arizona. Two analyses were performed. The first used photographs of tree lizard venters to quantify gular colors. The second used photographs of unrestrained male and female lizards in the field to obtain darkness of both lizard dorsums and backgrounds.

Colors in a photograph are subject to variation in ambient lighting, exposure, type of film, processing and other factors, and therefore standardization of each photograph is necessary. This is accomplished by taking additional photographs of a color standard (GretagMacbeth 1998) with lizard photographs (Figs. 1, 2).

For ventral photographs, Kodachrome ISO 64 transparency film was used with a fully manual SLR camera, so that each photograph was taken with the same exposure and aperture (f-stop 11, shutter speed 1/60). All photographs on a single roll of film were taken under identical conditions: either under photographic lamps indoors; or in the field, under shade, using a macro ring-flash with a manual setting (Vivitar 5000 Macro Flash). Each photo on a single roll of film was taken with the same subject to camera distance and the camera in a fixed position on a tripod. These procedures virtually eliminated the effects of ambient lighting, as was demonstrated by shooting exposures with the same setting without flash or lamps which resulted in nearly black photographs. A photograph of the color standard (Fig. 1) was taken at the beginning of each roll, serving as a standard for the subsequent photographs of lizards. Ventral photographs were taken of 43 male tree lizards, while they were restrained on top of an 18% neutral gray background (Fig. 1) along with a mm ruler.

For dorsal photographs, Kodachrome 200 transparency film was used with a fully manual SLR camera and a telephoto lens on a tripod. All dorsal photographs were of free-ranging tree lizards in situ (Fig. 2), that had been previously bead-marked (Fisher and Muth 1989), allowing identification of individual lizards. The lizard was then replaced by the color standard, which was also photographed (Fig. 2) using the same settings and conditions of the previously photographed lizard. This assures consistent exposure, aperture and lighting of each lizard photograph with the respective color standard photograph. We present data here on 233 male and 91 female tree lizards. To avoid psuedoreplication, individual lizards were used only once in each analysis presented here (dorsal and ventral color).

The film was developed into transparencies (slides), using the same developer (A&I, Hollywood, California, USA; K-14 Process) to assure consistency of quality. Transparency photographs of the lizards and color standard were digitized by scanning each image of the lizard and color standards with a transparency scanner (CanoScan FS2710), resulting in a 3600 x 2400 pixel RBG digital image. All automatic and color correction options on the scanner and software were turned off. Digital imaging software (Scion Image, available at: http://www.scioncorp.com; although this software has now been replaced by ImageJ: http://rsb.info.nih.gov/ij/) was used to correct for color biases in lizard photographs by calibrating with the respective known values of the color standard. We accomplished this by separating each image into three digital layers which represent hue, brightness (or % reflectance) and chroma (or saturation) each as optical density (Fig. 1). The hue and brightness layers were calibrated by using regressions between the actual hue and brightness of the color standard and the optical density of hue and brightness layers, respectively. This was done with the 'calibration' function in Scion Image. The actual hue values were those provided with the color standard. Reflectance of the gray samples in the standard were determined empirically with spectrophotometric analysis (results not presented,

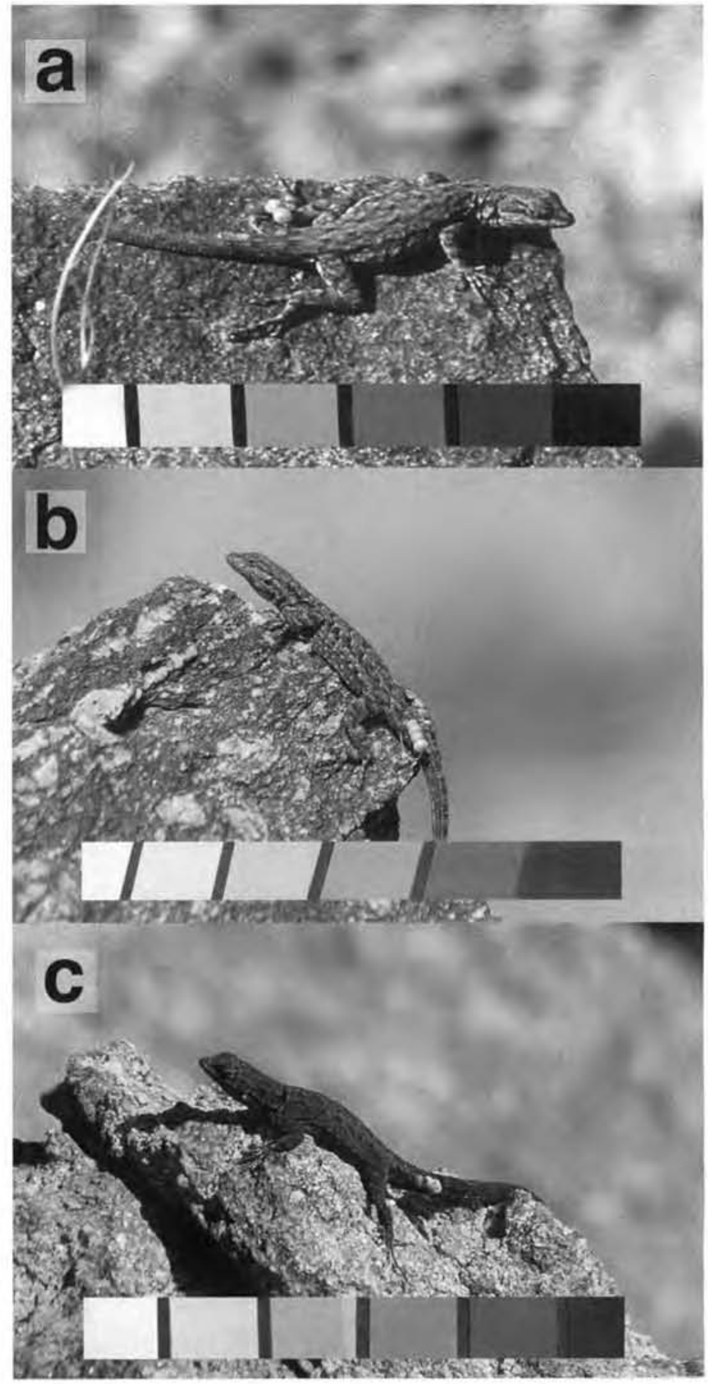

Fig. 2. Examples of three lizard photographs and their corresponding photographs of a color standard: a) female, b) light colored male, and c) dark male. Grayscales taken with each lizard photograph are included as insets in each photo.

data available upon request). Scion Image allows for the calibration regressions to be linear or nonlinear. Most of the calibrations used in this study were linear, and some were a second or third degree polynomial. The choice of model depended on the shape of the correction curve, and some corrections achieved a higher R^2 for this regression with a nonlinear correction model. The calibrations attained from photos of the color standard were then applied to lizard photographs, thus removing the potential biases of film, developing, and digitizing, from the images.

Using the 'measure' tool in Scion Image, optical density of a color patch in either the hue or brightness layer was then measured, resulting in either a hue score between 0–360 representing the 360 degrees of a color wheel, or a brightness score of 0–100%, representing total percent reflectance across the entire visible spectrum. Spatial scale was calibrated using the mm ruler in each ventral photo and the 'Set Scale' option in Scion Image. Using photos thus corrected for hue and linear measurements, we measured size and hue of both inner and outer throat patches. Using photos corrected for reflectance, we measured percent reflectance of both the lizard dorsum (excluding the head, neck, legs and tail) and a representative sample of rock background (Fig. 2).

Results

Digitally derived hues of throat patches and digitally measured reflectance of dorsal darkness were highly correlated with values of the color standard. The average regression between known hue values and hues obtained from photos for throat patches resulted in a $R^2 = 0.95$. The average regression for dorsal darkness had an R^2 of 0.98. These measures indicate a high degree of accuracy in predicting hue and darkness, respectively.

Analysis of throat patch sizes and hues of male tree lizards at Sierra Estrella revealed a great deal of continuous variation (Figs. 1, 3) with some individuals that could be categorized as monomorphic for throat hue. These individuals were at 0% difference in hue degrees between patches. Individuals were categorized as having either more or less than 10% of their throat patch made up of a central color, although there was a large amount of variance in this variable, with several individuals possessing central patches comprising 40% or more of the total patch.

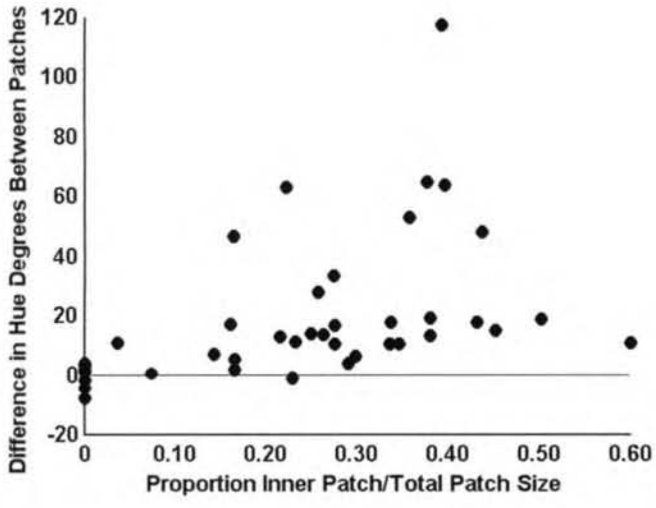

Fig. 3. Throat colors of male Ornate Tree Lizards, as described by contrast in hue and size proportion of the central and peripheral throat patches.

From the dorsal reflectance analysis, both sexes tended to have low percent reflectances, usually below 10% (Fig. 4). Furthermore, the backgrounds they rested on had similarly low reflectance, and females rested on slightly darker backgrounds than males, although not significantly so (two-tailed t-test, $p = 0.220$). Last, males tended to be darker than females (one-tailed t-test, $p = 0.002$, Fig. 4).

Discussion

Throat Color.—This study found that male tree lizards at Sierra Estrella exhibit largely continuous variation in the two throat patch variables: difference in hue between the inner and outer patch and proportion of the total patch comprised of the inner patch. Some individuals could be unambiguously assigned to a monomorphic throat class: those individuals that intercepted the y-axis in Fig. 3. However, among other individuals, considerable variation existed in both size and hue axes. Many individuals had a large inner patch (e.g., >30% of the total patch size) and possessed an inner patch that either perfectly matched, or greatly contrasted with, the outer patch in hue. This continuous variation in throat colors differs from the dichotomous morphs described in Thompson and Moore (1991). The discordance between studies might reflect differences in methodologies or geographic variation in signal design. Application of the methods described herein to several populations might address these possibilities.

Dorsal Darkness.—Males and females showed variation in dorsal reflectance, and males were darker than females. These data agree with those of Zucker (1994), who found that male tree lizards in some populations change color to signal social status. Further application of these methods will reveal if darker males may be sacrificing the degree of crypsis exhibited by females in order to convey their dominance status. Furthermore, because dark coloration might incur thermoregulatory cost, with darker animals heating faster (Norris 1967), dorsal darkness might indicate a handicap or honest signal. This is another possibility that might be explored using these techniques.

Color Methods.—The methods described herein allow simultaneous examination of patch size, shape, hue and brightness. These techniques allow quick and objective measurements to be taken of animal colors, and for dorsal colors, without the stress of handling. The high R^2 values for calibration of hue and reflectance obtained here show that the values obtained are consistent and accurate. These accuracies were consistent with different cameras, lenses, films (two types mentioned above), developers (as tested with an additional developer not used in the results herein), as well as ambient (sun, clouds, etc.) and artificial (lamps vs. flash) lighting. Data not presented here indicate that saturation of color, or 'chroma' may similarly be estimated with such methods with an R^2 of 0.80 (P. Hamilton, unpubl. data). It is important to note that the method described herein does not account for UV (ultraviolet) signals. This is not likely a limitation in the study system described here given that color patches of *U. ornatus* do not contain a strong UV signal (P. Hamilton and J. Macedonia, unpubl. data).

An obvious extension of these methods would be to use digital photography, rather than digitizing film photographs. There should be no problem applying such methods, with the one exception

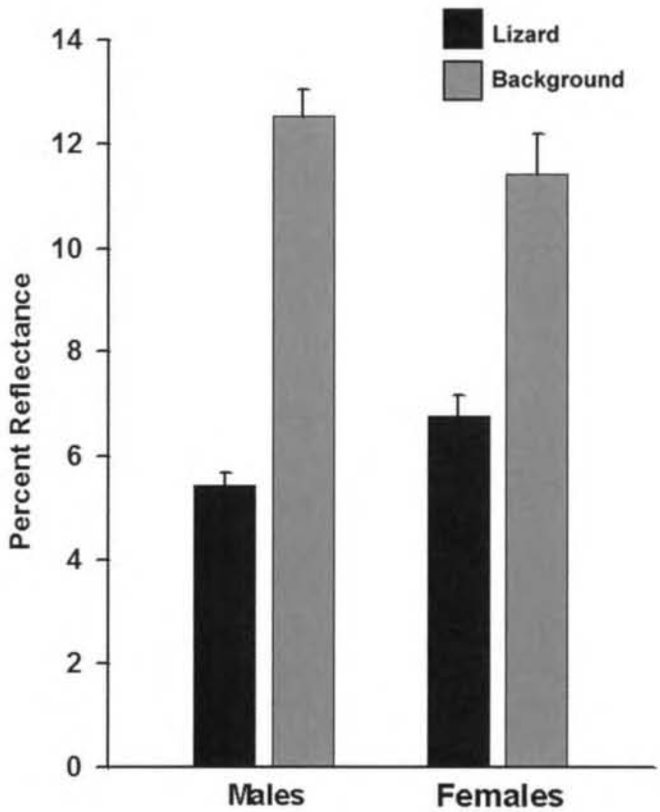

FIG. 4. Dorsal reflectance of male and female Ornate Tree Lizards, and their respective backgrounds.

that each photograph of an animal needs to be taken exactly the same as that of the standard. Many digital cameras do not offer such capabilities, and in particular, flash output can not always be standardized. Further methodological advances using similar methods may be able to measure additional spectral information, such as UV, from digital images. Another potential application of such methodology would be by applying various photographic filters, one may selectively measure reflectance of a specific wavelength (Chiao et al. 2000). Thus, a grayscale image can be produced in which the value of each pixel represents the reflectance of the UV bandwidth, the range of spectral sensitivity for a particular photoreceptor, or any other bandwidth of concern. Thus, one could obtain images that exactly correspond to an animal's perception of color (e.g., Webster and Mollon 1997). Such methodology could also be extended to produce images that match the perception of potential competitors or predators (e.g., Sumner and Mollon 2003).

In summary, analysis of animal color patterns in nature is fraught with conceptual and logistical difficulties. Researchers have generally dealt with animal color quantification in one of two ways: human-based (color chips) and technology-based (spectrophotometric) methods. A third alternative, that contains elements of each traditional method, uses standardized digital images. By the careful application of a photographic standard, one can eliminate nearly all potential biases in photographs (e.g., lighting, film, developing, digitizing). It is possible then to extract from such photos the three variables commonly used to classify colors: hue, brightness, and saturation. Additionally, dimensions of color patches may be simultaneously evaluated. We use such methods to evaluate two applications of lizard color quantification: throat polymorphism and dorsal darkness in Ornate Tree Lizards, *Urosaurus ornatus*. For throat polymorphism, we measured the size and hue of throat color patches in male *U. ornatus*. This allowed us to evaluate a new quantitative and objective method for traditional ranking of throat polymorphism types. For dorsal darkness, we evaluated dorsal reflectance of free ranging tree lizards, and described the variation found in this elusive, plastic character. These methods could easily be applied to similar systems in which classification of colors is crucial to hypothesis testing, such as *Uta stansburiana* (e.g., Sinervo and Lively 1996). Additionally, studies of the effects of color on thermoregulation (e.g., Pearson 1977) could benefit from the application of techniques that can assess total reflectance as an indicator of solar energy absorption of animals *in situ*.

Acknowledgments.—Ron Rutowski, John Sabo, John Alcock, Joe Macedonia, and Matt Kwiatkowski reviewed the manuscript and offered helpful improvements. Michael Moore, Michael Douglass and Kimberley Hughes reviewed preliminary analyses. This research was carried out under a scientific collecting permit from Arizona Game and Fish and an ASU IACUC animal care protocol. The research was conducted at Estrella Mountain Regional Park under a generously provided special use permit. Funding was provided from an ASASU research grant to PSH.

A New Trap Design to Sample Small Terrestrial Lizards

VINER F. KHABIBULLIN
and
MARINA V. RADYGINA
Faculty of Biology, Bashkir State University
Ufa, Bashkortostan 450074, Russia
e-mail (VFK): KhabibullinVF@ic.bashedu.ru

A variety of techniques have been proposed to facilitate collecting small lizards including pitfall and wire-mesh traps (Doan 1997; Simmons 1987), sticky traps (Glor et al. 1992; Whiting 1998; Downes and Borges 1998), and baited traps (Zani and Vitt 1995). Several specialized techniques for capturing lizards have been developed as well including the use of sticky poles (Durtsche 1996), mechanical grabbers (Witz 1996), an exotic Vietnamese trapping technique (Ziegler 1999), and mesh barriers to facilitate hand capture (Paterson 1998). However, each of these methods has limitations for capturing some lizard species. Here we describe a relatively simple trapping method, a tube-trap, to capture small terrestrial lizards that use small mammal burrows or similar terrestrial crevices as retreats.

The tube-trap is constructed from a 2-L plastic bottle to form a transparent cylinder approximately 160–180 mm long and 30–35 mm in diameter. The top and bottom of the bottle are cut off to obtain a rectangle approximately 110 x 180 mm and the long edges are fastened together with glue to form a cylinder (Fig. 1). A circle end cap is glued from the outside to one end, and from the other end a transparent door is attached by two fine wires that allow the door to swing in but not out. The diameter of the door should be slightly smaller (2–3 mm) than the diameter of the cylinder. A ring 3–4 mm in width is glued to the outside of the door end to prevent the door from opening outwards. The end cap, ring, and door are made from another 2-L bottle.

We tested this trap during June–July 2002 in South Urals, Russia on the sand lizard *Lacerta agilis*, primarily in steppe and semi-forest habitats. In the field we chased lizards into refuges such as holes or crevices in the ground. Then we set the traps into these holes with the door end of the tube facing into the hole (if the crevice was too large relative to the trap, soil was used to fill in the gaps). We left the trap for 1.5 h while searching for other lizards. Within this time, lizards emerged from deep within their retreats and entered the tube-traps by pushing the door inwards as they attempted to reach the surface. The one-way opening of the door does not allow animals to escape from the trap. The tubes are easy to monitor for captures because they are transparent.

Our total sampling period was 20 d (1260 trap/h). We set nine traps for 7 h (1000–1700 h) daily and checked them every 1.5 h. All animals found in the trap were removed and later released. No mortality was observed. Thirty-nine animals were captured in the tube-traps: nine males (23.1%) and 30 females (76.9%). Therefore, the tube-trap appears to be an effective tool for capturing these small lizards in terrestrial retreats.

There are several advantages of the tube-trap design: it is simple and inexpensive to make, compact and easy to transport, it can be positioned in a variety retreats, and it does not injure animals or require that they be removed from glue. Thus, the tube-trap should be useful for surveying and monitoring populations of other terrestrial lizards.

Acknowledgments.—This research was conducted in accordance with institutional standards for animal welfare (Protocol #5(82)) at Bashkir State University and a collecting permit (Permission #117) issued by the Ministry for Extraordinary Situations and Ecological Security of the Republic of Bashkortostan.

Marking Hatchling Turtles via Intraperitoneal Placement of PIT Tags: Implications for Long-term Studies

CHRISTOPHER L. ROWE

Turtles provide excellent models for ecological, evolutionary, physiological, and toxicological studies of long-lived animals. In such studies, it is often necessary for individual turtles to be marked for long-term identification. Several techniques exist for permanently marking individuals, including notching or drilling of the carapace, external attachment of metal or plastic tags, and internal injection of a coded, Passive Integrated Transponder (PIT) tag. Each of these methods has advantages and disadvantages, depending on research goals and study duration. While carapace alteration has been successfully used in numerous population-level studies (e.g., Cagle 1939; Gibbons 1987), there is a finite number of mark combinations, limiting the number of animals that can be identified. Furthermore, marks may become obscured or indistinguishable from marks resulting from natural shell damage, and physical disfigurement of animals may be undesirable. External tags, which have been used most extensively in sea turtle research, may be lost or rendered unreadable after only a few years (Balazs 1985, 1999; McDonald and Dutton 1996).

An alternative to the above marking methods is the use of implanted PIT tags, inert glass-encased microchips and electromagnetic coils encoded with unique alphanumeric labels, which are activated and recorded by a handheld reader. The PIT tag system is undoubtedly a superior method for animal marking with respect to long-term retention and readability. When properly implanted, these tags rarely corrode or break, and will theoretically remain operable for the lifetime of the individual. One-hundred percent tag retention and readability over an extended period of time with an absence of detectable negative effects on marked animals have been reported for several reptile species, including caiman (Dixon and Yanosky 1993), Leatherback Seaturtles (McDonald and Dutton 1996), Red-eared Sliders (Buhlmann and Tuberville 1998; Runyan and Meylan, *in press*), Florida Cooters and Florida Red-bellied turtles (Runyan and Meylan, *in press*), and garter snakes (Keck 1994).

A drawback to the use of PIT tags is that animals marked only in this manner are not readily identifiable as study animals without the proper scanning device. This problem is easily remedied by combining PIT tagging with a visible external mark common to all tagged animals, if appropriate. While the costs of employing PIT tagging was once prohibitive for many research programs, recent reductions in cost have made the systems affordable to a greater number of investigators. Currently, PIT tag scanners may be purchased for less than US $400 and tags for approximately US $4–$6 each.

Specifically, marking of hatchling turtles in a manner that will remain unambiguous over long time periods presents a unique challenge. Techniques used for marking large juvenile or adult turtles generally are inappropriate for very small individuals. Often it is difficult to notch the carapace of a hatchling turtle so that the mark will remain discernable as the individual grows, and placing a metal or plastic tag on rapidly-growing external tissues can exacerbate the risk of tag loss and possibly impede movements by the juvenile. Whereas PIT tags have been successfully implanted into adult turtles in shoulder muscle (Balazs 1999), the inguinal region of the body cavity (Buhlmann and Tuberville 1998), and subcutaneously into a limb (Balazs 1999; Willem Roosenburg, pers. comm.; pers. obs.), the current minimum size of available PIT tags (2 mm diameter x 12 mm long) precludes intramuscular or subcutaneous insertion into hatchlings without causing severe trauma. Thus, in this study we explored an alternative technique for implanting PIT tags into hatchlings that would minimize trauma while remaining detectable for a long period of time.

We tested the efficacy of insertion of PIT tags into the peritoneal cavity of juvenile Painted Turtles (*Chrysemys picta*), as has been done successfully in hatchling caiman (Dixon and Yanosky 1993) and snakes (Keck 1994). We were interested in determining whether hatchling turtles could be tagged in such a manner without affecting survival or growth. Additionally, we monitored tag retention and readability for nearly one year following implantation.

Turtles used in this study were four weeks post-hatching (absorption of external residual yolk was complete) and were derived from five laboratory-incubated clutches. The clutches were obtained from gravid *C. picta* females caught between 22 May and 7 June 2002 in southern Maryland. Oviposition was induced using intraperitoneal injections of oxytocin at a dosage of 20 IU/kg (Ewert and Legler 1978). We randomly selected eight individuals to be tagged from a pool of 18 hatchling turtles. Hatchlings were randomized in such a manner that at least one individual from each clutch was included in each of the two treatment groups. Wet mass and carapace length (CL) of each individual were measured prior to insertion of PIT tags, at the time of tagging, and on three subsequent dates. When size variables were later analyzed it became apparent that average initial sizes of tagged individuals exceeded

TABLE 1. Summary statistics and comparisons of juvenile traits in tagged and untagged individuals. Results are presented as means ± 1 SE (when applicable). CL = carapace length.

Treatment	$N_{initial}$	Initial mass (g)	Initial CL (mm)	Survival (%)	Final mass (g)	Final CL (mm)	Instantaneous growth rate (mass: g^{-1})	Instantaneous growth rate (CL; mm^{-1})
Tagged	8	4.75 ± 0.18	24.9 ± 0.30	87.5	13.38 ± 2.49	39.0 ± 2.7	0.079 ± 0.016	0.032 ± 0.01
Untagged	10	3.81 ± 0.16	23.1 ± 0.25	80	11.88 ± 2.23	36.9 ± 2.8	0.084 ± 0.16	0.033 ± 0.01
		P = 0.001	P = 0.001		P = 0.661	P = 0.590	P = 0.829	P = 0.937

those of untagged individuals. Mean initial measurements (± 1 SE) for wet mass and CL were 4.75 ± 0.18 g and 24.9 ± 0.30 mm for tagged individuals and 3.81 ± 0.16 g and 23.1 ± 0.25 mm untagged individuals (Table 1). The differences in both initial mass and initial CL were statistically significant at the beginning of the study, yet sizes of the two groups had converged by the end of the study (Fig. 1). Both the long duration of the experiment and the nearly identical growth rates and trajectories of the two groups (Table1, Fig. 1) suggest that initial size differences did not influence the results.

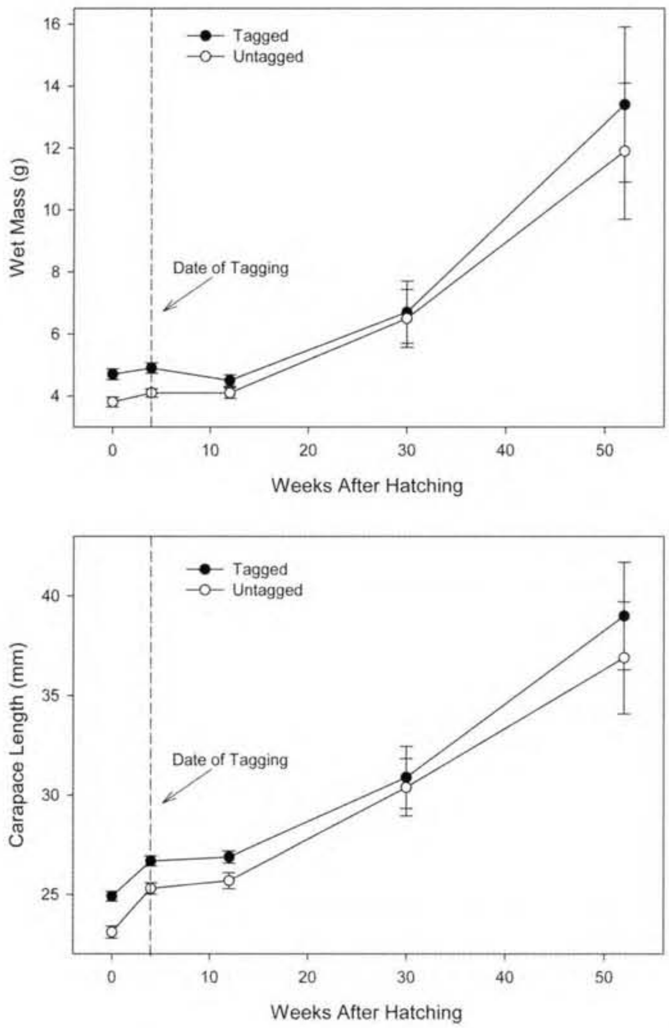

FIG. 1. Growth trajectories based upon change in mass (upper panel) and change in carapace length (lower panel) for tagged and untagged *Chrysemys picta* hatchlings monitored from August 2002 until September 2003 at the Chesapeake Biological Laboratory in Solomons, Maryland. Data presented are means ± 1 SE.

Individuals to be tagged were blotted dry and the skin of the left inguinal fossa was cleaned with a topical antiseptic (10% povidone-iodine solution). A sharp 1 mm internal diameter PIT tag insertion needle and tag (1 x 12 mm, model TX1400L, Biomark Inc., Boise, Idaho), and a blunt probe were soaked for ca. one minute in 91% isopropyl alcohol prior to loading the tag into the needle. After extending the left hind leg, the needle was placed beveled-edge upwards against the taut abdominal skin midway between the limb and the plastron. Pressure was gently applied until only the bevel of the needle pierced the skin. Thus the shaft of the needle did not enter the body cavity, minimizing wound size and potential contact with internal organs. As the needle was maintained in position, the tag was slowly pressed through the incision using the plunger of the needle until the tag was completely expelled from the needle. The result of this procedure was insertion of the PIT tag into the peritoneal cavity, with the rearmost portion (< 1 mm) of the tag protruding through the incision. The sterilized blunt probe was then used to gently push the protruding end of the tag into the cavity.

We observed no blood loss during or after the tagging procedure, probably because integumentary and peripheral vascularization is minimal in this region of the body. Immediately after insertion of the tag, the incision was cleaned with 10% povidone-iodine solution, re-dried, and treated with an antiseptic liquid bandage containing 1% 8-hydroxyquinoline (New Skin™, Medtech, Jackson, Wyoming) which served to seal the incision and protect it from infection. Tagged individuals were placed in individual 800 ml plastic containers that contained a paper towel moistened with a 5% dilution of household chlorine bleach in well water. At two-day intervals over the following ten days, individuals were retreated with New Skin and the towels were replaced.

During the first few days of the ten-day post-operative period, the tags in two individuals were partially expelled from the body cavity (< 2 mm extended outside of the body cavity). These tags were gently re-seated with a sterile probe prior to being re-treated with povidone-iodine solution and New Skin™. Note that in subsequent work with adults of other species in which tags were placed subcutaneously in a limb, we have found that the use of an adhesive (Locktite™ Super Glue, Henkel Consumer Adhesives, Avon, Ohio) similar to that currently used in human medicine (e.g., Wood et al. 1992) resulted in 100% tag retention over 3–4 week post-tagging. Thus this product might prove more effective for closing tagging sites than the compound employed in the current study. At the end of ten days, all tagged individuals were examined to ensure that the incision had visibly closed. Additionally, all individuals

received unique identifications painted onto the carapace using non-toxic acrylic paint that was reapplied as needed. None of the animals in either group was fed until after the 10-day period because hatchlings of this age were likely still resorbing internal yolk stores (despite prior absorption of the external portion of yolk).

Following the post-operative holding period, mass and CL were measured in tagged and untagged individuals, and then all turtles were released into a common holding tank containing 19 L of well water. This and all subsequent measurements of mass of tagged turtles were corrected for the mass of the tag. Turtles were fed and water was changed at two to three-day intervals for the duration of the study. Food consisted of a gelatin-based aquaculture fish food containing 50% protein (Aquatic Eco-systems, Apopka, Florida) mixed with ground whole fish and shellfish. During the study, the laboratory in which the turtles were held was maintained between 21 and 24°C and light was provided by overhead fluorescent lights (12 hours light:12 hours dark) supplemented with natural light from a southwest-facing window 2 m from the holding tank.

Individuals were measured and weighed at 1, 4, and 11 months post-tagging. Turtles were also scanned to verify tag retention using a Biomark Pocket Reader EX (Biomark Inc., Boise, Idaho) and examined for general health.

Final wet mass, CL, and growth rates were compared using two-sample *t*-tests. Instantaneous growth rates in mass and CL over the course of the study were calculated as:

$$[\ln(\text{final mass or CL}) - \ln(\text{initial mass or CL})] / 11 \text{ months}$$

(Ricker 1979)

A Type I error rate of $\alpha = 0.05$ was used for all statistical tests.

All animals retained their tags for the duration of the study and we were successful in detecting all tags with the scanner. One turtle partially expelled its tag (< 1 mm protruded through the skin) during the first month after release into the holding tank. This tag was re-seated as described above. Survival, wet mass, and CL did not differ between treatments (Table 1). Growth trajectories are shown in Figure 1. Instantaneous growth rates over the course of the study did not differ between tagged and untagged individuals (Table 1). We did not observe any detectable changes in behavior between groups that might influence survival probabilities of turtles released into the wild.

The results of this study suggest that PIT tags can be successfully injected into the peritoneal cavity of hatchling turtles without affecting growth and survival. Because *C. picta* is characterized by relatively small hatchling body sizes, it is likely that this technique could also be applied to other species characterized by small hatchling size.

The study was terminated in August 2003, when the turtles were one year post-hatching, and therefore we do not know how much longer the tags would be detectable by the scanner. As the turtle grows, it is possible that the tag will become more difficult to detect because of the addition of bone and flesh that might block communication between the tag and the scanner. However, used on full power and in optimal orientation to the body, most PIT tag scanners have a communication distance of 6–30 cm, depending upon the type of scanner used (www.biomark.com). In addition, the other investigations cited in this report suggest little migration of PIT tags from their original implantation site. For example, Buhlmann and Tuberville (1998) and Keck (1994) found that PIT tags injected into the body cavity become attached in place by coelomic membranes or other connective tissues, minimizing migration and potentially allowing identification of individuals as they achieve a considerably larger size. Because our study lasted less than one year, we do not know how long the PIT tags would remain detectable as the turtles grow beyond the size achieved here.

Acknowledgments.—We appreciate the assistance of K. Richardson during the project. Thorough reviews provided by S. Mullin and E. Blankenship greatly improved the content of the manuscript. Increases in Capture Rates of an Aquatic Snake (*Seminatrix pygaea*) Using Naturally Baited Minnow Traps: Evidence for Aquatic Funnel Trapping as a Measure of Foraging Activity

CHRISTOPHER T. WINNE
University of Georgia, Savannah River Ecology Laboratory
Drawer E, Aiken, South Carolina 29802, USA
e-mail: winne@srel.edu

The secretive nature of most snake species can hinder efforts to understand aspects of their ecology and population biology unless systematic capture techniques are employed and potential sampling biases are recognized (Parker and Plummer 1987). For herpetofauna other than snakes (e.g., amphibians, lizards, and turtles) numerous studies of collecting methods and sampling regimes have resulted in standardized methods, with well-elucidated biases (e.g., Dodd 1991; Dunham et al. 1994; Gibbons 1990; Heyer et al. 1994; Willson and Dorcas 2004; Willson et al. 2005). Several collection techniques have been used successfully for terrestrial snakes (reviewed in Fitch 1987, 1992), such as terrestrial drift fences with pitfall and funnel traps (Gibbons and Semlitsch 1981), road cruising (Dodd et al. 1989; Mendelson and Jennings 1992; Seigel and Pilgrim 2002), visual encounter surveys (Sun et al. 2001), and artificial cover objects (Fitch 1992; Grant et al. 1992). For capturing snakes in aquatic habitats most studies have relied upon visual encounter surveys, opportunistic captures, or aquatic funnel traps (Casazza et al. 2000; Gibbons and Dorcas 2004; Madsen and Shine 2000; Seigel et al. 1995a; Seigel et al. 2000), but the effectiveness and biases of these methods have seldom been examined experimentally (e.g., Willson et al. 2005).

Keck (1994) demonstrated that aquatic funnel traps can be used to successfully capture snakes in aquatic habitats and that baiting funnel traps with dead prey items (e.g., fish and amphibians) can increase capture rates. Here I chose a blocked experimental design that would allow a further, more powerful test of whether baiting traps increases capture rates of aquatic snakes. By design this experiment also examines whether aquatic snakes randomly enter funnel traps during movements or if they seek out funnel traps due to foraging behavior, thereby providing insight into some of the potential biases of aquatic trapping.

This experiment was conducted from 4–25 June 2003 at Ellenton Bay, a protected Carolina bay wetland located on the U.S. Department of Energy's Savannah River Site in South Carolina. Ellenton Bay is an ideal locality for aquatic trapping experiments because (1) it generally supports large populations of aquatic snakes, including the focal study species, *Seminatrix pygaea* (Black Swamp Snakes; Winne et al. 2005) and (2) it is dominated by shallow water (< 1 m deep) and relatively uniform distributions of emergent grasses (predominantly *Panicum* spp.), water lilies (*Nymphaea odorata*), and water shields (*Brasenia schreberi*), thus reducing variability in capture success attributable to heterogeneous habitat distributions. Traps were set in shallow water with approximately 3–5 cm of the trap above water to reduce the possibility of drowning captured snakes. Two varieties of commercially available cylindrical funnel traps, designed to capture minnows (i.e., minnow traps), were used during the study: steel (model G-40; Cuba Specialty Manufacturing Company, Fillmore, New York) and plastic (model 700; N.A.S Incorporated, Marblehead, Ohio). Steel funnel traps were 42 cm long and 19 cm in diameter, and constructed of galvanized steel mesh (mesh openings = 0.6 cm wide). Plastic funnel traps were 43 cm long and 16 cm in diameter, and had slightly smaller mesh openings (0.4 cm wide). All of the funnel traps had two funnels, one on each end of the trap (openings 2.5 cm in diameter), that extended 11 cm inwards towards the center of the trap. Throughout most of the study a total of 36 plastic and 30 steel funnel traps was used (i.e., 18 and 15 pairs, respectively); however, some pairs were not used during the first few days of the study.

Aquatic funnel traps were set in pairs (traps within a pair < 1 m apart) and within pairs each trap was randomly assigned to serve as either a "baited" or an "unbaited trap." This blocked design removed any variation in trap success that could be due to microhabitat differences. Rather than actively baiting traps with dead prey items, baited traps were allowed to naturally accumulate (i.e., self-bait) live larval amphibians (e.g., tadpoles and salamander larvae) throughout the study. In contrast, the unbaited traps were emptied of their contents daily. At Ellenton Bay aquatic funnel traps rapidly accumulate amphibian larvae; as a result, unbaited traps were not always truly unbaited. However, because all snakes were captured after the second trap night, baited traps always contained substantially more larval amphibians than unbaited traps. Traps were checked daily and all snakes were taken to the lab, where sex (presence or absence of hemipenes), snout–vent length, mass, and reproductive state (determined by palpation, Seigel et al. 1995b) were recorded. All snakes were individually marked (branding) and released at their point of capture. All predatory aquatic insects were removed daily from both baited and unbaited traps.

I captured 47 adult *S. pygaea* over 1758 trap nights. I used Chi-squared tests to test the null hypothesis that there were equal numbers of captures in baited and unbaited traps. There was an obvious bias in captures towards baited funnel traps: 79% of all snakes ($\chi^2 = 15.51$, $p < 0.001$) and 88% ($\chi^2 = 9.94$, $p = 0.002$) of all pregnant females were captured in the baited traps (Fig. 1). Capture rates (trap nights/captures) were over 3 times higher in baited traps (4.2% vs. 1.3%).

The majority of *S. pygaea* were captured in baited funnel traps despite having an equal chance of encountering the unbaited funnel traps located less than 1 m away. This result confirms Keck's (1994) finding that baiting increases capture rates of aquatic snakes and demonstrates the benefits of allowing traps to self-bait (e.g., Seigel et al. 1995; Winne et al. 2005). The strong bias in capture rates of baited funnel traps suggests that the majority of the aquatic trap captures were due to foraging behavior rather than random entry into traps. Indeed, Seigel et al. (2000) noted that another natricine snake, *Thamnophis marcianus*, often feeds on tadpoles inside aquatic funnel traps. Consequently, captures of snakes in aquatic funnel traps may be biased towards foraging individuals, a result which has important implications for inter- and intraspecific comparisons of relative abundance within snake communities.

There are at least four reasons why inter- or intraspecific differ-

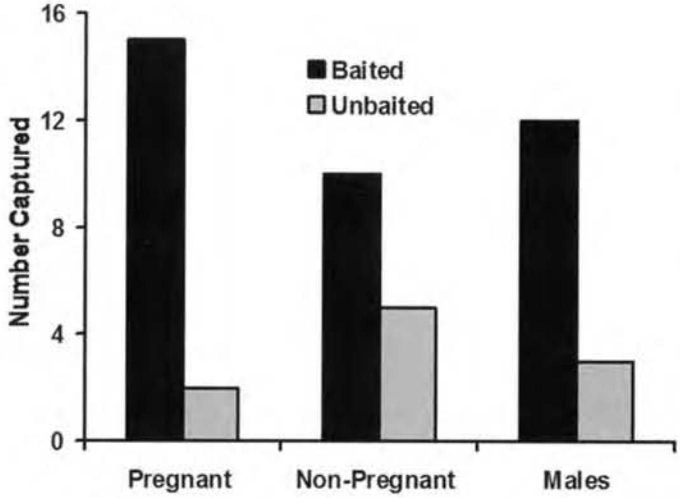

FIG. 1. Number of pregnant and non-pregnant female and male *Seminatrix pygaea* captured in baited vs. unbaited aquatic funnel traps at Ellenton Bay in June 2003. Overall, 79% of snakes ($\chi^2=15.51$, $p<0.001$) were captured in baited traps.

ences in foraging ecology could lead to biased estimates of relative species abundance or sex ratios in aquatic funnel traps. First, if species/sexes differ in foraging mode (i.e., active vs. sit-and-wait foragers) funnel trap captures may be biased towards the species/sex that is a more active forager. Second, if species/sexes differ in their diet any potential capture biases of funnel traps towards certain prey species/sizes could translate into biases towards the species/sex that forages for that particular prey species/size. Third, in studies specifically comparing capture rates over time or among sites, capture rates may differ because of differences in accumulated bait. Lastly, if species/sexes differ in seasonal patterns of active foraging funnel traps might result in biased estimates of relative abundance during some seasons.

The current study species, *S. pygaea*, may serve as one example of how intraspecific differences in foraging ecology might translate into biased estimates of relative abundance using baited minnow traps. Based on aquatic funnel captures, the Ellenton Bay population of *S. pygaea* is significantly female biased during May and June, but the sex ratio is equal during other parts of the year (Winne et al. 2005). This seasonal change in sex ratio is strongly correlated with sexual differences in foraging ecology. During May and June pregnant *S. pygaea* contain food items significantly more frequently than adult males (unpublished data), presumably because males are searching for mates instead of foraging for prey. In contrast, in other months of the year, when the sex ratio at Ellenton Bay is equal, males are frequently found with food items (unpublished data), indicating that they have resumed foraging.

No single collection method is without biases (Fitch 1992), including aquatic funnel trapping. Despite some inherent biases, aquatic funnel traps are effective at capturing large numbers of highly secretive aquatic snakes (*Farancia* spp., *S. pygaea*, and *Regina rigida*; Willson et al. 2005), which are particularly difficult to collect using other conventional methods (e.g., visual encounter surveys, terrestrial sampling; Gibbons and Semlitsch 1991). Further, aquatic funnel traps provide an excellent method for systematically tracking demographic changes in aquatic snake populations (e.g., Madsen and Shine 2000; Seigel et al. 1995a) because they allow for highly repeatable sampling regimes and greatly reduce observer biases associated with visual observation and hand collecting techniques (Casazza et al. 2000; Keck 1994). The results of this study clearly demonstrate that aquatic funnel traps are most effective when baited and highlight the importance of considering some of the potential sampling biases inherent to this technique.

Acknowledgments.—B. Lawrence assisted with checking the funnel traps. M. B. Keck, R. A. Seigel, J. D. Willson, and one anonymous referee provided insightful comments on this manuscript. Collection of animals was in conformance with all appropriate collection permits and animal care protocols. This research was partially supported by the Environmental Remediation Sciences Division of the Office of Biological and Environmental Research, U.S. Department of Energy through Financial Assistance Award No. DE-FC09-96SR18546 to the University of Georgia Research Foundation.

Detectability of a Large-bodied Snake (*Sistrurus c. catenatus*) by Time-constrained Searching

DANIEL S. HARVEY
Department of Natural Resources and Environmental Sciences
University of Illinois at Urbana-Champaign, 606 East Healey Street
Champaign, Illinois 61820-5502, USA
e-mail: harvey_da@yahoo.ca

Detectability of vagile species is an important consideration when surveying populations. Without an approximation of the proportion of individuals present that are detected by a given method, it is difficult to determine how well relative measures represent true population values (Boulinier et al. 1998; Burnham and Overton 1979; Hyde and Simmons 2001; Norvell et al. 2003). This difficulty can be compounded if detectability varies by time (Bonnet et al. 2002), temperature (Royle 2004), habitat (Hyde and Simmons 2001; Prior et al. 2001; Weatherhead and Charland 1985; Weatherhead and Prior 1992), or segment of the population (Martin 1993; Prior et al. 2001). For cryptic taxa such as snakes, detectability should be a particularly important factor because most individuals in a given area may not be seen. Despite its importance, detectability is generally not considered in field studies that estimate abundance of snakes (e.g., Mendelson and Jennings 1992; Seigel 1998; Stevenson et al. 2003; Sullivan 2000).

Large-bodied, sedentary snakes (e.g., rattlesnakes) tend to avoid traps and artificial shelters (Fitch 1992; Ryan et al. 2002). For these species, time-constrained searches (searching a set area in a given amount of time) may be the most efficient method of surveying the population. Rattlesnakes can be detected both visually and by hearing the rattle. Determining the detectability of snakes in time-constrained searches will provide an empirical foundation for population estimates, and a standard with which to evaluate alternative methods of detection. Using snakes equipped with radio transmitters, I tested how often, and under what conditions, individual Eastern Massasauga rattlesnakes (*Sistrurus c. catenatus*) were found by time-constrained searches when the snake was known to be present.

Methods.—I opportunistically captured Massasauga rattlesnakes for use in the study by searching suitable habitat on the Bruce Peninsula, Ontario (Weatherhead and Prior 1992). I implanted 7 adult snakes (2 non-gravid females, 5 males) with temperature-sensitive radio transmitters (Model SI-2T, Holohil Systems Inc., Ontario) in 2002 and 2003 as part of a separate study. Surgical procedures generally followed Reinert and Cundall (1982). Post-surgery, snakes were held for three days and then released at their point of capture. Snakes carrying implanted transmitters in this and other studies appeared to behave normally over extended time periods, although there is little comparative data from non-implanted snakes or experimental evaluation of the impact of implanted transmitters on behavior (Harvey, pers. obs.; Lutterschmidt and Reinert 1990).

Each detectability trial was conducted by two individuals, a tracker and a searcher. After locating a snake with a transmitter, the tracker established a 50 x 50 m square around the snake using string. The snake's position within the square was randomly determined for each trial using coordinates derived from a random number generator (Excel 2002). The searcher, naïve to the snake's location other than it was somewhere within the square, was given 20 min to find the snake. Based on preliminary trials this was considered sufficient time to search the entire area at a steady pace. Upon completion of each trial, the temperature of the snake was determined from the transmitter pulse rate, and the percent of the snake that was visible from above was recorded to the nearest 25%. If a snake was located by the searcher, the time required to find the snake and method of detection (audible, visual) were noted.

Of the 61 trials conducted in June and July 2004, no more than two trials were conducted per snake per week, with each snake used in an equal number of trials overall (8 or 9 each). Trials were conducted during the day (0930–1600 h) in fields, marshes, and forests, and in a range of weather conditions. Trials were split equally between two experienced and fourteen inexperienced searchers. Experienced searchers had observed massasauga rattlesnakes in the wild more than 500 times each, whereas inexperienced searchers had fewer than 20 observations each prior to the trials. To avoid inexperienced searchers improving at finding snakes over the course of trials, no individual conducted more than four trials. To estimate variance in detection rates I applied the bootstrap technique with 1000 replications (Efron and Tibshirani 1993).

Results.—Snakes were successfully located in 9 of 61 trials (14.8%, SD = 4.6%). Searchers usually passed near snakes during trials but the snakes did not respond by movement or rattling. Only in 3 cases was the snake completely hidden during the trial. Neither the experience of the searcher nor the habitat the snake was in affected whether a snake was found (Table 1). Snakes were found most often at intermediate temperatures (20–30°C; Table 1). No

TABLE 1. The number of Eastern Massasauga rattlesnakes found visually and by hearing the rattle during 61 searching trials on the Bruce Peninsula, Ontario. Observations are grouped according to four factors. The mean probability (p) that the detection rate was independent of each factor was determined using chi-square tests with 1000 bootstrap replicates.

	Searcher experience		Snake temperature (°C)			Habitat			Snake visibility (%)				
	Experienced	Inexperienced	<20	20–30	>30	Field	Marsh	Forest	0	25	50	75	100

Total	3	6	0	7	2	4	3	2	0	0	2	4	3
p	0.31			0.11			0.40				0.07		

snakes were found visually when <75% visible and no snakes were found at all when <50% visible. All snakes found visually were stationary when detected. Snakes at intermediate temperatures were more visible than cool snakes (<20°C) or hot snakes (>30°C) ($F_{2,58} = 3.10$, $p = 0.05$). Low detection rates prevented us from testing for interactive effects between factors or determining the relationship between each factor and the time required to locate snakes in successful trials.

Discussion.—Snakes known to be present were detected by searching a 2500 m^2 area for 20 min in approximately 1 in 7 trials. Snakes were detected most often when their body temperatures were intermediate (20–30°C) and when they were more visible. Under weather conditions leading to intermediate body temperatures, when snakes were more likely to bask, detectability improved to 1 in 4 snakes.

The physiologically optimal body temperature range in snakes is an evolutionarily conservative trait and tends to be between 28 and 34°C (Lillywhite 1987). Massasauga rattlesnakes may be more likely to respond to disturbance by rattling when near physiologically optimal temperatures (Prior and Weatherhead 1994). In this study, however, most snakes were found visually. Snakes were more exposed when their body temperatures were just below their probable physiological optimum, presumably to warm themselves, which made them more visible to searchers. At body temperatures below 20°C, however, snakes were more concealed. This may signal a shift towards crypsis as the means of defense when low body temperatures reduce motor performance (Mori and Burghardt 2004). Conclusions regarding the effects of all factors on detectability should be considered tentative given the modest sample sizes and lack of testing for interactive effects.

All trials were conducted with non-gravid females and males. Gravid females of many viviparous species use habitat with less ground or canopy cover than males or non-gravid females to assist in embryonic development (Lourdais et al. 2004; Reinert 1993). The use of more exposed habitat would likely make gravid females easier to detect than males or non-gravid females (Bonnet and Naulleau 1996), but that remains to be tested for Massasauga rattlesnakes.

Knowing that Massasauga rattlesnake detectability was low, can one use a measure of detectability to estimate the actual number of snakes present in an area sampled? Using similar search methods, Weatherhead and Prior (1992) encountered Massasauga rattlesnakes in my study area at a rate of 0.18 snakes/h. Assuming they searched under the same range of weather conditions, and thus detected only 1 of every 7 snakes present, the number of snakes in the area they sampled would have been 7 times higher than encountered. Deriving abundance estimates in this manner requires two important caveats. First, estimates based on low detection rates (<30%) are more likely to be biased than estimates based on higher detection rates (MacKenzie et al. 2002). Second, search effort (thus, detectability) may be somewhat inflated in situations where snakes are known to be present relative to snake surveys when presence is unknown. A more conservative way to use detectability estimates to improve snake surveys is to incorporate the factors that affect detectability into the study design. For example, by always conducting surveys under the same weather conditions, estimates of abundance should always have the same bias. In terms of sampling efficiency, conducting surveys only under conditions where detectability is high (e.g., cool, sunny days when snakes are basking) may result in more snakes being found per unit search effort. At the very least, researchers should be aware that population estimates based on time-constrained searches may be seriously underestimated, and that the extent of the underestimate can vary with environmental conditions.

Acknowledgments.—Funds for this project were provided in part by the Parks Canada Species at Risk Recovery Action and Education Fund, a program supported by the National Strategy for the Protection of Species at Risk. Additional funding was provided by the Interdepartmental Recovery Fund of the Canadian Wildlife Service. I wish to acknowledge B. Toms and numerous volunteers for participating in trials. P. Weatherhead, R. N. Reed, P. May, P. Zorn, and an anonymous reviewer provided feedback that improved the manuscript. The project was supported and based at Bruce Peninsula National Park under the supervision of F. Burrows, Park Ecologist. The following research was conducted in compliance with animal care protocols at the University of Illinois at Champaign-Urbana and research permits from Bruce Peninsula National Park.

Little information is available on post-breeding movements, habitat requirements, and mortality of northern leopard frogs (*Rana pipiens*) because they disperse into upland or other wetland habitats following reproduction and are difficult to detect (Waye 2001). Radio telemetry is used to examine these characteristics in other taxa, however, its usefulness for studying *R. pipiens* has not been established. An obstacle in deploying telemetry to study movement is finding a transmitter attachment method that does not adversely affect the animal's health and behavior and allows tracking over several months. The objective of our study was to evaluate existing external and internal radio transmitter attachment methods and adopt or develop a technique appropriate for *R. pipiens*.

Radio telemetry has been used to study movements of several ranid species, including *R. draytonii*, *R. luteiventris*, and *R. clamitans* (Bulger et al. 2003; Pilliod et al. 2002; Lamoureux et al. 2002). Researchers have used external belts or harnesses to attach transmitters to anurans (Bartelt and Peterson 2000; Bull 2000; Goldberg et al. 2002; Matthews and Pope 1999; Waye 2001; Hodgkison and Hero 2001; Watson et al. 2003; Muths 2003). A few studies successfully used surgical implantation as a method of radio tagging frogs (Goldberg et al. 2002; Lamoureux and Madison 1999; Werner 1991), as well as fish and salamanders (Beaumont et al. 2002; Colberg et al. 1997).

Surgical implantation has some advantages over harness attachment, including reducing skin lesions and rates of transmitter loss (Werner 1991). However, achieving the proper level of anesthetic without compromising survival is difficult (Goldberg et al. 2002; Green 2001). Prior to our study, surgical anesthesia had been tested in the laboratory (Goldberg et al. 2002; Lamoureux and Madison 1999), but it was unclear if it could be successfully performed in the field. In addition, the postsurgical fate and longevity of *R. pipiens* carrying implanted transmitters was unknown.

We evaluated four types of external attachments: nickel bead chains, aluminum bead chains, plastic cable ties, and sewing elastic in the field. When the belt attachments proved unsatisfactory for our purposes, we tested two types of internal attachment tech-

niques on frogs in the laboratory: subcutaneous and peritoneal implantation. Following the laboratory studies, we tested the efficacy of peritoneal implants on *R. pipiens* in the field. We tracked these individuals for several months post-surgery to assess the usefulness of the transmitters for monitoring habitat use and movement over time.

We attached radio transmitter harnesses (model BD-2GHX, 1.85 g, 165 MHz band, 20-week life, whip antenna; Holohil Systems, Ltd., Carp, Ontario, Canada) to 26 wild *R. pipiens* adults from August to October 2000. Transmitters did not exceed 5–6% of the frog's total weight, below the 10% threshold recommended by Richards et al. (1994). We tested nickel (N = 15) and aluminum bead chain (N = 8) (Rathbun and Murphey 1996), plastic cable-ties (N = 8), and sewing elastic (N = 5) to find a harness material that allowed long-term radio tracking of individual frogs without restricting movements or causing injury to the frogs. Plastic cable-ties were plastic fasteners with a self-locking end, usually used in household or light mechanical applications. The sewing elastic was purchased at a fabric store; the cut ends were joined by thread stitches. Transmitters were attached to the harness by running the harness material through a rigid plastic tube affixed to the transmitter package by the manufacturer. The harness was attached around the waist of the frog so that the transmitter rested on the lower back of the frog just above the vent (Fig. 1). After shedding belts, several of the same frogs were refitted with a new harness; a total of 36 attachments were evaluated. Frequent escapes from the nickel bead chain belts within the first few weeks made it necessary to confine frogs in 1.8 m x 1.8 m enclosures placed along the edge of the wetland. Subsequent tests of aluminum bead chain, plastic cable ties, and sewing elastic harness materials and their effects on incidence of injury, transmitter loss, and behavioral changes were tested on frogs in the enclosures. On 12 October, the remaining 4 frogs in the enclosure were released and tracked with the telemetry equipment to their overwintering burrows. We estimated how far external radios could be detected with our receivers.

Subcutaneous and peritoneal surgical implantation techniques were developed and evaluated in the laboratory during winter 2001.

FIG. 1. Northern Leopard Frog (*Rana pipiens*) with external transmitter and whip antenna attached with elastic harness. (Photo courtesy of United States Geological Survey.)

Holohil model BD-2GHX radio transmitters weighing 1.85 g with an internal loop antenna coated with epoxy resin were implanted using surgical procedures similar to those described by Goldberg et al. (2002). Other scientists with experience in anuran surgical implantation techniques were also consulted to refine the procedure (G. Birchfield, University of Missouri, Columbia, Missouri and S. Heppell, United States Environmental Protection Agency, Corvallis, Oregon, pers. comm.).

Nineteen *R. pipiens* adults weighing > 15 g, purchased from a biological supply company (Ward Biological Supply, Rochester, New York, USA), were held for several weeks prior to surgery to ensure that they were healthy and feeding. Frogs were fed live crickets daily. Immediately prior to surgery, frogs were anesthetized by placing them in a 1-gallon glass (3.79-liter) jar containing an aqueous solution of 0.02% tricaine methanesulfonate (MS-222, Finquel™, Argent Chemical Laboratories, Inc., Redmond, Washington, USA) buffered with sodium bicarbonate to pH 7 and kept at room temperature (22–23°C). The MS-222 solution was deep enough that the frogs could just hold their heads above the surface of the solution with all four feet on the bottom of the jar. A frog was deemed appropriately anesthetized for surgery when it did not right itself when placed on its back and was generally unresponsive to touch (ca. 2–5 min.; smaller frogs were anesthetized faster). All surgical instruments and transmitters were sterilized with Benz-all™ (12.9% benzalkonium chloride solution, Xttrium Laboratories, Chicago, Illinois, USA); sterile gloves were used for each surgery. Anesthetized frogs were placed on a damp sterile sponge on their right side. An incision about 15 mm in length was made with surgical scissors through the skin and underlying muscle and peritoneum (peritoneal implant only) along the left side of the frog near the center axis (Fig. 2). A radio transmitter was inserted through the incision and under the skin (subcutaneous implant) or into the peritoneal cavity, avoiding excessive pressure on the internal organs. A Polysorb 6/0 suture package with a reverse cutting needle (United States Surgical Corporation, Norwalk, Connecticut, USA) was used to close the incision. The peritoneal incision was closed with a continuous suture technique with the single-instrument tie knot at the beginning and end of the incision (Summerfelt and Smith 1990). The skin incision was closed with 4–5 simple interrupted sutures with the single-instrument tie knot. After suturing, the skin incision was treated topically with Bactine™ antiseptic spray. Frogs were closely observed until they recovered from the anesthetic and were kept in the laboratory for up to 19 weeks post-surgery to assess transmitter loss, and health and behavioral effects. Frogs were weighed and snout–vent length measured at the time of the surgery and also weighed at the end of the study or at the time of death. At the end of the study, all live frogs were euthanized by emersion in MS-222 (Green 2001) and a necropsy was performed.

In spring and summer 2001 and 2002, 90 wild *R. pipiens* adults weighing approximately 30 g or more were captured adjacent to their breeding site (i.e., pond or wetland) and received peritoneal implants of radio transmitters (Holohil BD-2GHX, 1.85 g, loop antenna). Three study sites were used in 2001 and two in 2002. The study area was located in Houston and Winona counties in Minnesota, part of the Driftless Area Ecoregion of North America. Rolling hills with steep riverine drainages and erosive soils support a less intensive agriculture than in many parts of the Mid-

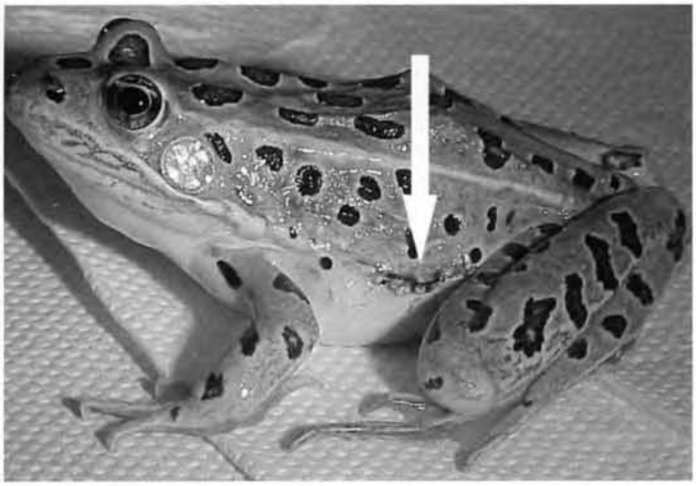

FIG. 2. Northern Leopard Frog (*Rana pipiens*) with transmitter surgically implanted showing incision location (arrow). (Photo courtesy of United States Geological Survey.)

west, with agriculture occupying 30–40% of the landscape, along with woodlands and some grasslands (McNab and Avers 1994).

We conducted our surgeries in the field near the capture site to reduce transport stress and avoid accidental transfer of diseases from the laboratory to native populations. In 2001, surgeries were conducted outside under a canvas tent and in 2002 surgeries were conducted in a vehicle. Frogs were observed closely for up to 4 h after surgery to monitor recovery from the anesthetic. Frogs were released and tracked from the ground with a hand-held Yagi antenna and receiver system (Advanced Telemetry Systems, Inc, Isanti, Minnesota, USA). Individuals were located 4–5 days per week during 2001 and daily in 2002; frogs were tracked from the time of implant until October, or until frogs died, radio contact was lost, or transmitters failed. To assess health status, some frogs with transmitters were weighed every 30 days following release during 2001. To minimize disturbance, frogs were not weighed after release in 2002. We estimated how far implanted radios could be detected with our receivers.

Of the 15 frogs fitted with nickel bead chain belts and released, 10 shed their belts within two weeks and the remaining frogs developed skin lesions and the belts were removed (Table 1). Of the frogs fitted with aluminum bead chain, sewing elastic, or plastic cable-tie belts and confined in enclosures, 18 of 21 harness attachments applied to these frogs failed within 1 to 3 weeks (transmitter was shed, Table 1). Eight of 11 frogs developed skin lesions within two weeks and 7 were released. Among the four frogs released with transmitters from the enclosure in October, one frog shed its transmitter within five days and the remaining three frogs were tracked for 14 days, when tracking ended.

Overall, external belts were tested on 26 frogs; the belts caused skin lesions in 14 frogs and transmitters were retained a median of 10 days after attachment (Table 1). Thirty transmitters were shed out of 36 attachments. None of the harness materials we evaluated performed satisfactorily. When we tightened the belts, the frogs developed skin lesions; when we loosened the belts, they shed them. We were able to detect external transmitters with whip antennas at distances ranging from 100 to 200 m in the field.

The time required to achieve a surgical level of anesthesia during our laboratory trials was short and variable (range = 1.5–3 min) despite constant environmental conditions. Most frogs began feeding within four days post-surgery and their incisions healed within two weeks of surgery.

During the first laboratory trial (surgery on 15 February 2001), three frogs received subcutaneous implants and four frogs received peritoneal implants (Table 2). During the subsequent trial (surgery on 2 March 2001), all 12 frogs received peritoneal implants. One of three frogs receiving subcutaneous implants in the first trial failed to recover from anesthesia and one frog experienced suture rupture after 19 days. The third frog retained its transmitter until the trial ended. We discontinued subcutaneous implants after the first trial because they created a lump on the frog's ventral surface that threatened to rupture the sutures. All four frogs receiving peritoneal implants in the first trial survived the surgery, 3 frogs lived from 6 to 49 days post-surgery, and the remaining frog lived to the end of the observation period (116 days, Table 2).

In the second trial with peritoneal implants, all 12 frogs survived the surgery, three frogs died within 10 days of surgery, one escaped from its cage after 95 days, and the rest survived to the end of the observation period (Table 2). After initial healing of the suture site, 8 of 12 frogs developed small skin lesions near the

suture site 31–68 days post-surgery; in four frogs these healed spontaneously. Nine of the 12 frogs continued to feed, behave normally, and gain weight (Table 2). Three frogs expelled their transmitters at 34, 89, and 98 days post-surgery, probably via the gastrointestinal system; we found no exit wounds elsewhere. The nine frogs that survived more than 10 days all gained weight (mean = 16.0 g ± 6.2 SD) by the end of the observation period. Overall, three transmitters broke through the skin shortly after surgery, three frogs expelled the transmitter, and necropsies revealed that four frogs had encased the transmitter in connective tissue adjacent to or inside the gastrointestinal tract (Table 2).

Among the 90 wild frogs surgically implanted with radio trans-

TABLE 3. Fate of frogs (*Rana pipiens*) undergoing field surgical implantation of radio transmitters, April–July, 2001–2002. Fate is the number of frogs experiencing that outcome: A) Failure to recover from anesthesia; PM) Killed by predator or mower; U) Frog found dead–unknown causes; T) Transmitter failure; M) Missing; R) Recovered transmitter without frog; and S) Survived to end of study.

mitters, 17 did not recover from the anesthesia. Eleven of the 17 mortalities were associated with elevated anesthesia solution temperatures (> 25°C). In the initial field surgeries, anesthesia solution temperatures were allowed to equilibrate with ambient (air) temperatures because this strategy had been successful in the laboratory. Two episodes of poor surgical survival associated with surgeries conducted on warm days led us to conclude that anesthetic solution temperatures might be the problem. We began to control the solution temperature to < 25°C, regardless of air temperatures, and subsequently 30 of 31 frogs survived the surgery.

Of 77 frogs that survived the surgery and were released, 27 frogs died (predators, N = 8; alfalfa mowers, N = 8; unknown causes, N = 11), 7 were recaptured live with transmitter failures, 27 were lost (fate unknown), 2 transmitters were recovered without the frog (fate of frog unknown), and 10 frogs survived long enough to enter hibernation (Table 3). Of the 11 frogs found dead due to unknown causes, 9 frogs died within 10 days and 2 frogs died within 60 days post-surgery. Eight of the deaths occurring within 10 days post-surgery occurred following a rapid decrease (from 25 to 0°C) in air temperatures. Sores near the incision, similar to those observed in the laboratory, were noted in three frogs. Frogs were tracked for up to 124 days post-surgery (median = 38.5 days). Three failed transmitters were sent back to the manufacturer for diagnosis; battery failure and component malfunction were identified as the causes.

In 2001, most frogs monitored (15 of 19) gained weight (mean = 12.8 g ± 14.7 SD). Most frogs were detected hiding in grass or near hedgerows of crop fields. We were able to detect transmitters with internal loop antennas at distances ranging from 50 to 75 m in the field and the longest single-day movement we observed for an individual frog was 313 m.

All external attachment techniques we tested proved inadequate for tracking *R. pipiens* over long time periods because frogs shed their belts quickly or developed lesions that required release. In comparison, *R. pipiens* with peritoneal implants were tracked for up to 4 months during our field study. Tracking durations reported from other studies deploying belts on anurans also have been relatively short, for example, 1–20 days for *R. pipiens* (N = 24, Waye 2001), 11–126 days for *R. luteiventris* (N = 71, Bull 2000), up to 30 days (mean = 16–21 days) for *R. sylvatica* (N = 11, Muths 2003), 5–12 days for *Eleutherodactylus augusti* (N = 5, Goldberg et al. 2002), 9–13 days for *Littoria nannotis* (N = 19, Hodgkison and Hero 2001). Twelve of 38 *Bufo boreas* shed their belts within two weeks (Bartelt and Peterson 2000). Further, nearly all studies reported skin lesions associated with the belts, although recent work by Muths (2003) using craft elastic strung with glass beads shows promise of belt retention without injury.

We found that nonrecovery from anesthesia was a major mortality factor for *R. pipiens* receiving surgical implants. Most surgical failures appeared to be associated with elevated MS-222 solution temperatures (> 25°C). Ambient temperature fluctuates more in the field than in the laboratory, so this problem did not arise during our laboratory trials. We ultimately achieved success in surgical implantation and recovery of the frogs using a mobile laboratory suitable for both the surgery and postsurgical observation of the frogs. After our surgical experiences, we found recommendations for limiting the temperature of MS-222 to ≤ 25°C when used as an anesthetic for amphibians (Green 2001).

Goldberg et al. (2002) also reported that achieving the appropriate level of anesthesia was the most difficult part of surgery, although temperature of the anesthetic solution was not mentioned. Werner (1991) implanted radio transmitters into six *Bufo americanus,* with no reported mortality using a 0.01% solution of MS-222 for 15–20 min. Lamoureux and Madison (1999) performed 23 surgeries on *Rana clamitans* with no reported mortality; they used a 0.5% solution of MS-222 to anesthetize the frogs, but did not report exposure times. Lamoureux et al. (2002) performed 27 surgeries on *R. clamitans* with one surgical death.

Laboratory testing of terrestrial salamanders has demonstrated that responses to MS-222 anesthesia vary among species and de-

pend upon both pH and concentration (Lowe 2004). Lowe also suggests using aqueous pH buffers to prepare the MS-222 rather than neutralizing the solution with sodium bicarbonate. It is likely that anurans also have species-specific responses to MS-222 (Green 2001). We conclude that reliable, safe application of MS-222 as a surgical anesthetic for amphibians is possible under controlled conditions (solution concentration, pH, temperature, and exposure time) and with some initial exploratory laboratory testing of the target species.

Presumably, the mortality of frogs that recovered from anesthesia but died from unknown causes within 10 days was related to the surgery. The majority of these deaths (8 of 10 frogs) coincided with a rapid decrease in ambient temperature within days of surgery. An early April period of warm temperatures in 2002 (highs >25°C) induced breeding behavior in adult *R. pipiens* and was followed by a temperature drop to near 0°C. Mortality may have resulted from the combined stress of recent emergence from hibernation, breeding activity, an extreme fluctuation in ambient temperature, and surgery. Avoiding this type of mortality will be difficult because of the need to implant transmitters while *R. pipiens* are concentrated at breeding ponds for brief periods in spring, a time of unpredictable weather conditions in the upper Midwest. Rudolph et al. (1998) also found that snakes implanted with radio transmitters had higher mortality when implants occurred late in the season when temperatures were colder. Frogs are at high risk of predation in the immediate post-surgical period because individuals vary in the time it takes to fully recover from anesthesia. Protecting frogs from predation during the surgical recovery period may improve immediate post-surgical survival. Field enclosures provide predator protection and concealment, but not climate-controlled conditions.

Although the surgical implants resulted in health effects, primarily mortality within 10 days of surgery, *R. pipiens* that survived past 10 days behaved normally and gained weight, both in the laboratory and in the field. Our laboratory trials indicated that frogs experienced low mortality from 10 to 134 days post-surgery, although some small skin lesions developed. In the field, frog mortality occurring after 10 days post-surgery was apparently unrelated to the surgery, as evidenced by good health (e.g., weight gain and apparently normal behavior). We observed that predation and hay mower strikes were the primary non-surgical mortality factors for *R. pipiens*. Ours may be the first direct evidence of mortality due to hay mower strikes reported from a telemetry study. This has obvious conservation implications for amphibian populations. For example, frequently-mowed hay fields located adjacent to amphibian breeding sites may reduce post-breeding survival.

Even surgical implantation does not ensure that frogs will retain the transmitters for the duration of studies. With subcutaneous implants, transmitters can break through the sutures and be lost within days of surgery. Conversely with peritoneal implants, some frogs retained transmitters a month or more before expelling them, presumably via the gastrointestinal tract. Shedding transmitters via the gastrointestinal tract also has been observed in fish (Marty and Summerfelt 1986), but to our knowledge, has not been previously described in frogs.

Another challenge to the use of internal implants with a highly mobile species like *R. pipiens* is the limited detection range that we observed for transmitters with internal loop antennas (50–75 m). Undoubtedly, this was a factor in the high rate of missing frogs (35%) we experienced. Likewise, Goldberg et al. (2002), using somewhat smaller transmitters, detected external transmitters at distances > 200 m, whereas detection was limited to 6–40 m with implanted transmitters. Although external implants have longer detection ranges, they may be of limited value in some studies because of their short retention times. If tracking frogs over several months is needed to meet study objectives, frogs may need to be tracked more frequently to reduce loss rates due to long distance movements between tracking events. In the case of *R. pipiens*, tracking events may need to occur at intervals shorter than 24 h. In summary, we believe surgical implantation holds the most future promise for tracking *R. pipiens* over relatively long periods with minimal health effects.

Our data indicate that both external belts and surgical implantations of radio transmitters can have significant health risks for frogs. For those studying movements of rare species, this presents a dilemma because high morbidity and mortality are unacceptable in small populations. We make several suggestions for limiting morbidity and mortality. First, we found that all attachment methods required significant skill and experience to be successful, a non-trivial problem for beginning researchers. We suggest that novices spend time practicing attachment techniques with someone skilled in the desired method. If possible, practice the technique on a common frog species similar in size to the target species, perhaps a species available from biological supply companies. Belt retention and skin lesion development may be species- and perhaps habitat-specific, therefore, we suggest testing the best available external belts on the target species in field enclosures. If external belts are retained long enough to achieve the research purposes without causing skin lesions, belts are the best solution. If not, proceed to surgical implantation.

Likewise, we recommend practicing the initial surgeries in the laboratory on a similar non-target species under the supervision of someone skilled in the technique. Because anesthetics and dosages are species-specific (Green 2001), anesthesia concentration, pH, exposure time, and temperature should be tested on the target species in the laboratory. Surgeries should be conducted under controlled conditions. If a vehicle is available that provides protection from adverse weather and temperature extremes, field surgeries can be done; otherwise, conduct surgeries in the laboratory. This decision will also depend upon the distance from the field site to the nearest laboratory. We recommend that frogs be protected from predation for at least 24 h post-surgery in the laboratory or in a field enclosure. Frogs should display feeding and/or escape behaviors before release. Track frogs at least daily and more frequently during wet weather to minimize loss of study subjects.

Large scale trapping protocols for snakes can be expensive and require large investments of personnel and time. Typical methods, such as pitfall and small funnel traps, are not useful or suitable for capturing large snakes. A method was needed to survey multiple blocks of habitat for the Louisiana Pine Snake (*Pituophis ruthveni*), throughout its historic range in Louisiana and Texas, to obtain presence-absence data and to obtain specimens for radio-telemetry studies (Himes et al. 2002; Rudolph and Burgdorf 1997; Rudolph et al. 2002).

We required a method that was feasible with respect to cost of materials, time necessary to service traps, ease of installation, and efficiency in capturing snakes. The trapping method needed to capture large, mobile species, but not small, litter-dwelling species. We ultimately designed a large four-entrance funnel trap, with extensive drift fence arms to guide snakes toward the trap opening. These traps have been in use since 1993 to survey large snakes in Arkansas, Louisiana, and Texas. This trap design also was used to examine the impact of roads and vehicle-related mortality on large snakes (Rudolph et al. 1999).

Traps consisted of 121.9 x 121.9 cm (48 x 48 in.) tops and bot-

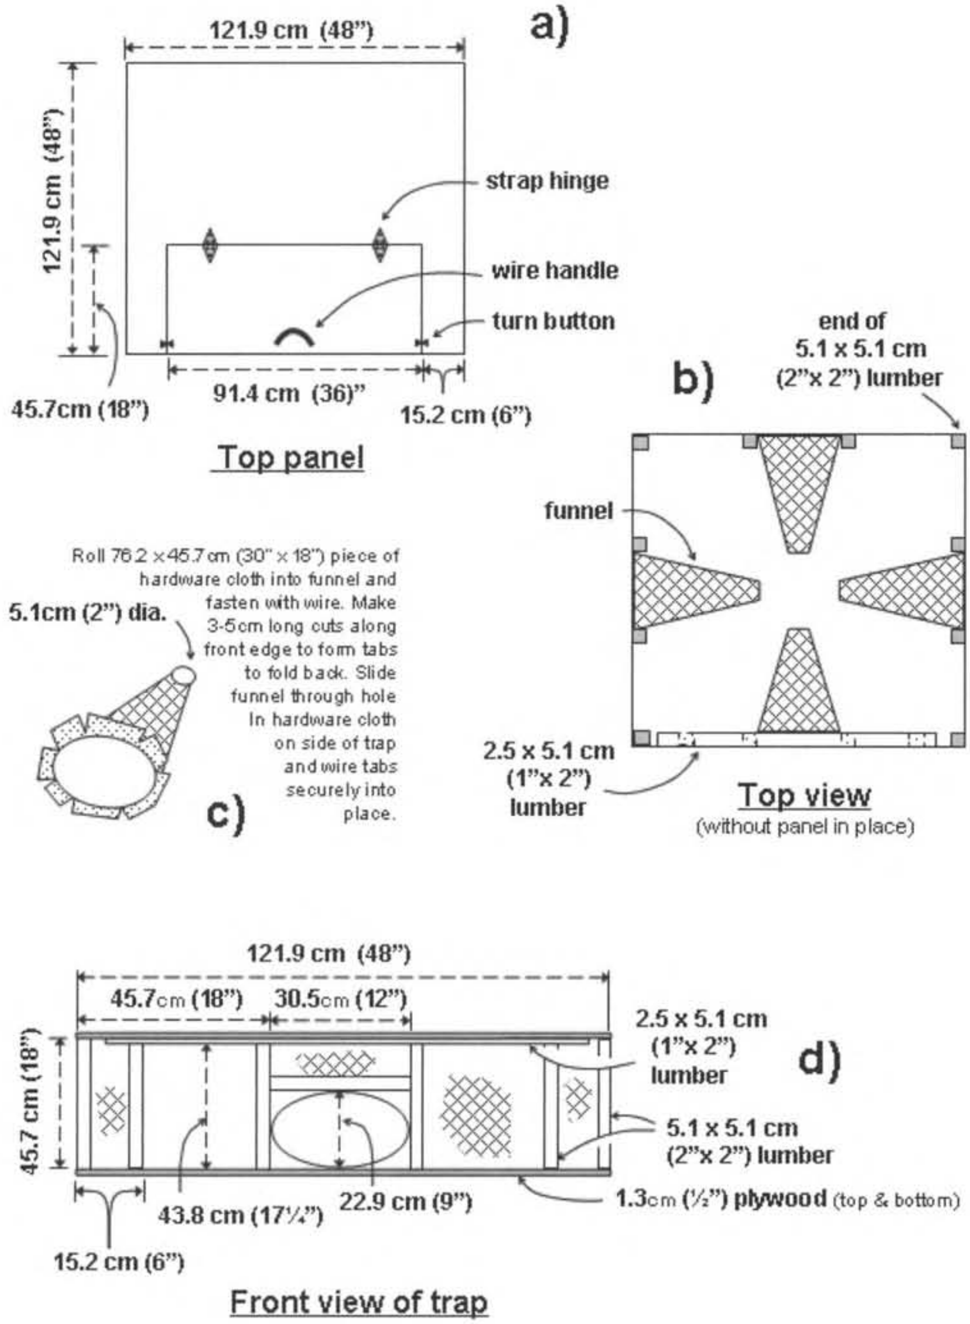

FIG. 1. Schematics of a successful trap design to capture large, mobile species of terrestrial snakes in eastern Texas a) top view of the trap b) top view of trap without top panel in place to show position of funnels c) an individual funnel and d) front view of trap. Trap dimensions and components are shown in English units of measurement to facilitate purchase from local building supply stores.

toms constructed of 1.3 cm (1/2 inch) treated plywood supported by wooden uprights 45.7 cm (18 inches) in height (Fig. 1). The sides were screened with hardware cloth (0.64 cm [1/4 inch] mesh). One or two hinged doors in the top of the trap allowed access for retrieval of snakes. Four funnel entrances of 64 cm (1/4 inch) mesh hardware cloth wired to the box at midpoint of each side allowed entrance of snakes (Fig. 1). Minimum diameter of the inner portion of the funnel was approximately 5.1 cm (2 inches).

Traps were installed by placing them on a soil surface that had been previously cleared and leveled. Excess soil was used to fill any gaps that would allow snakes access beneath the traps. Drift fences were constructed of 6.4 mm (1/4 inch) mesh hardware cloth approximately 15 m (50 feet) in length and 61 cm (2 feet) in height (Fig. 2). Longer drift fences could be used if desired. Drift fences were installed perpendicular to each side of the trap beginning at the midpoint of the funnel entrance. Fences were buried approximately 10 cm in depth and braced with wooden stakes or short pieces of iron reinforcement bar as required. Small pieces of hardware cloth were cut to fit, inserted part way into the funnel opening and wired to the drift fence to keep snakes from going around the terminus before entering the funnel (Fig. 2). Mesh size, height, and length of drift fences could easily be varied to capture snake

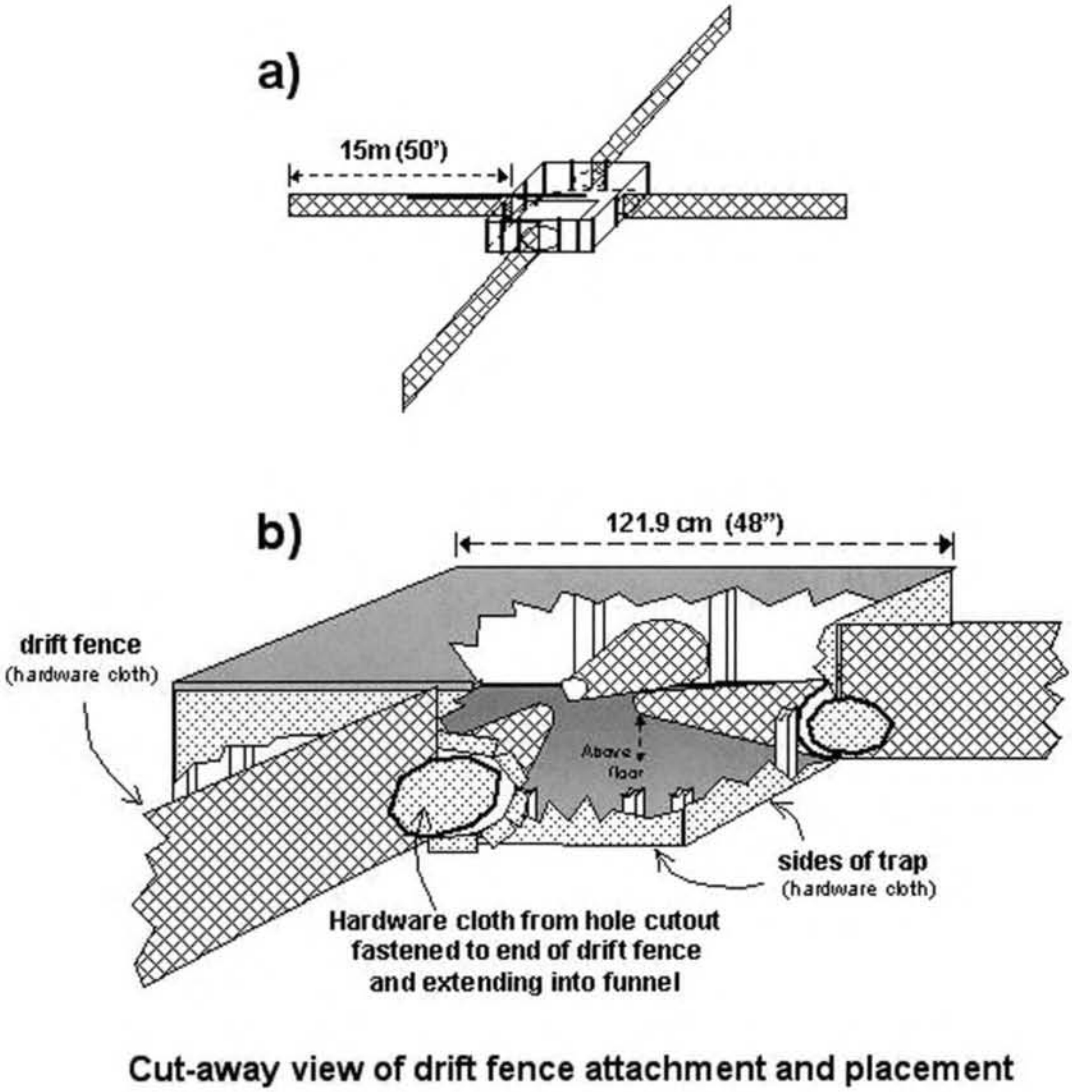

FIG. 2. More schematics of the trap design a) full view of the trap and drift fences and b) a cut-away view of drift fence attachment and placement.

species of varying body sizes. Other commonly used drift fence materials such as sediment cloth or metal flashing could also be used. Funnel traps may be placed at distal ends of each drift fence to increase capture rates. In addition, each trap was supplied with a 3.8 liter (1 gal.) chick watering source. When possible, traps were installed in situations that provided some shade to further reduce stress on captured individuals. Snake traps were constructed using treated wood, making them very durable. We have had traps in the field continuously in use for up to 6 years, in both wet and dry forest situations. These traps are in good condition and are still serviceable. See Table 1 for list of materials.

Trap success varied depending on site characteristics. However, in the upland pine habitat where most of our effort has been directed, we captured an average of 7.5 snakes (large species only) per trap per season during the early March to late October trapping period (240 trap days). Snake capture data for an array of 15 traps located in Nacogdoches Co., Texas, from 1999–2002, approximately 13,920 trap days, indicate the diversity of species captured (Table 2). These data documented a significant range extension for the Glossy Snake, *Arizona elegans* (Collins et al. 2001), and

5.1 x 5.1 cm (2 x 2 in.) treated lumber, 2.4 m (8 ft) long	4
2.5 x 5.1 cm (1 x 2 in.) treated lumber, 1.2 m (4 ft) long	1
0.64 x 0.64 cm (1/4 x 1/4 in.) mesh, hardware cloth 61 cm (24 in.) wide	
30 m (100 ft) roll for drift fences	2
8.5 m (28 ft) piece for trap & funnels	1
7.6 cm (3 in.) strap hinge	2
turn button	2
20-gauge galvanized wire 15 m (50 ft)	1
nails (or screws), box of 100	1
heavy duty staple gun and box of staples	1

TABLE 2. Snakes captured in 15 traps located in Nacogdoches County, Texas from 1999 to 2002.

Scientific name	Common name	No. Captured
Arizona elegans	Glossy Snake	4
Coluber constrictor	Racer	10
Elaphe obsoleta	Eastern Ratsnake	44
Heterodon platirhinos	Eastern hog-nosed Snake	1
Lampropeltus calligaster	Yellow-bellied Kingsnake	11
Masticophis flagellum	Coachwhip	79
Nerodia fasciata	Southern Watersnake	1
Agkistrodon contortrix	Copperhead	49
Agkistrodon piscivorus	Cottonmouth	7
Unidentified species	Skeleton in trap	18

suggested that the Louisiana Pine Snake, *Pituophis ruthveni*, might not occur at this site.

The trapping protocol resulted in some snake mortality, primarily because of occasional infestations of imported fire ants (*Solenopsis invicta*). We used a variety of commercially available ant poisons to treat all visible mounds within approximately 10 m of the traps. This was generally sufficient to control ants within the traps. During the four-year period of trapping, 30 snakes died in our traps, an average of 7.5 snakes per year, or 13.3% of the snakes captured. We also suspected that ophiophagous snakes such as Common Kingsnakes (*Lampropeltis getula*) and Prairie Kingsnakes (*L. calligaster*) occasionally entered traps and consumed other captured snakes.

The design of our traps resulted in few small litter-dwelling species being captured. This presumably resulted from their reluctance to leave the litter surface and ascend the inclined funnel to enter the trap, and the fairly large mesh size that allowed very small individuals to pass through. Adjustments in funnel orientation and mesh size would easily allow the trap to be tailored to specific needs. The use of 3.2 mm (1/8 inch) mesh hardware cloth for the trap, funnels and drift fences would permit the capture of smaller species of snakes. However, it should be noted that the finer mesh hardware cloth tears easily compared to the 6.4 mm (1/4 inch) mesh hardware cloth and requires more support when used for drift fences.

Taxa other than snakes were frequently captured in the traps. The capture of invertebrates, amphibians, and reptiles presented few problems. However, the capture of birds and small mammals resulted in considerable mortality. Birds, in particular, had very short survival times in the traps, as they tended to injure themselves attempting to escape. Reducing the size of the funnel entrance from 8–10 cm to < 5 cm prevented larger mammals (skunks, opossum, squirrels) and most game birds (quail) from entering the traps, and had no obvious impact on capture rates for snakes. Small passerines could still get in the traps. However, more frequent checking on a daily basis would reduce mortality of trapped animals.

This trap design, especially in conjunction with the long drift fences, was quite effective at capturing large terrestrial snakes. The large size of the trap itself and the water source was intended to limit the number of trap visits to once per week. However, in our study we had a higher mortality rate of captured snakes than expected, largely because of fire ants that are common in our region. More frequent trap visits and fire ant eradication would have likely reduced the amount of mortality. We suggest that our trap design in conjunction with efforts to reduce snake mortality, such as ant control, placing traps in shade when possible, and daily trap visits, should maximize success in capturing large terrestrial snakes.

Acknowledgments.—We thank J. Keel for several design and construction improvements that improved trap utility. Research was conducted under Texas collecting permit (SPR-0490-059). Initially, in 1993 we checked traps weekly because we assumed that the large trap design and watering system would limit mortality and allow longer intervals between checks. However, our observations of mortality in traps checked weekly support the recommendation to check traps daily as suggested in the ASIH Animal Care Guidelines (see Guidelines for Use of Live Amphibians and Reptiles in Field Research, American Society of Ichthyologists and Herpetologists; http://www.asih.org/pubs/herpcoll.html.).

This article describes the rattlebox, an apparatus designed to study learning in rattlesnakes (genera *Crotalus* and *Sistrurus*). The rattlebox is relatively inexpensive, simple to construct, and can be adapted to study several learning paradigms. First, we describe the construction of an automated box that consistently induces rattling. Second, we report preliminary results of a study of habituation of the rattling response in three Western Diamondback Rattlesnakes (*Crotalus atrox*). Finally, we suggest potential uses of the apparatus for studies of classical and operant conditioning.

Learning can be defined as a "relatively permanent change in behavioral potential as a result of experience" (Abramson 1994). Countless studies have been published which assess the learning capacities of gold fish (*Carassius auratus*), pigeons (*Columbia livia*), white rats (*Rattus norvegicus*), and dogs (*Canis familiaris*) under various learning paradigms ranging from habituation to classical conditioning and operant procedures. While much has been discovered about learning processes using these traditional "laboratory species," a true phylogeny of learning will require experiments with a greater number of non-traditional species (Bitterman 1965). Further, behavior (and performance in learning tasks) can be used as characters in phylogenetic analysis (de Quieroz and Wimberger 1993), which by its very nature requires a much broader taxonomic scope. Snakes are one such group in which noticeably few learning studies have been published. There are probably several reasons for this paucity.

Burghardt (1977) noted the difficulties encountered in performing learning experiments with snakes. Among these difficulties are their relative inactivity (snakes spend a large proportion of their time sedentary), a general lack of positive reinforcement (most snakes consume large meals infrequently [although see Burghardt et al. 1973, Holtzman et al. 1999, Kleinginna 1970, and Begun et al. 1988 for exceptions]), and a limited number of dependent variables in which to measure (the tubular body form of snakes suggests a rather simple behavioral repertoire relative to other vertebrates).

Rattlesnakes are noticeably lacking from studies of learning probably because of the limitations listed above along with the relatively large body size of some species and handling difficulties associated with their venomous nature. One dissertation (Mills 1970) describes attempts to use escape and avoidance contingencies with Sidewinder (*C. cerastes*) and Mojave (*C. scutulatus*) rattlesnakes. Mills concluded that while escape response topography was subject to change, true avoidance was not trainable in his three subjects. It should be noted that in studies of avoidance and escape it is important to consider the study animal's "species-specific defensive response" (Bolles 1970). Thus, dependent variables appropriate for rattlesnakes should include occurrence of rattling, latency to rattling, and duration of rattling, along with the prototypical striking, and flight behavior that have been utilized in previous learning studies of colubrids. With the first three dependent variables in mind, we have designed an apparatus that consistently releases the rattling response and allows for easy quantification of latency and duration.

The purpose of the rattlebox is to repeatedly apply an invariable stimulus to a test subject that consistently results in the subject rattling its tail. Previous studies have used stuffed animals (LaDuc 2002), predator effigies (Shipman 2002), or a human observer (Duvall et al. 1985) to elicit defensive behavior from rattlesnakes. However, because the experimenter presents each of these, there is variation among presentations in the way they are perceived by the test subject. Additionally, whenever a human observer serves as the stimulus, they risk being envenomated by the test subject. The apparatus diagrammed in Fig. 1 reduces inter-presentation variation and the risk to the experimenter of being bitten.

The rattlebox is a simple 60 cm (L) x 64 cm (W) x 60 cm (H) box in which a moveable top is affixed to heavy-duty cabinet drawer slides that allow it to slide open horizontally. To reduce the possibility of pheromones influencing behavior, we built the prototype out of plywood covered with latex paint. We also covered the bottom of the rattlebox with newsprint that was changed following each training session. If pheromones are an issue, or the object of investigation, we suggest that the plywood be replaced with Plexiglas. Plexiglas is easier to clean and less likely to be contaminated by potentially confounding odors.

A snake is introduced into the apparatus through a 6.5 cm diameter keyhole located at the lower center of one side of the box. Snakes are coaxed into the box with a snake hook via this opening, which is closed with a swinging door. A clear acrylic barrier is located on the inside ca. 18 cm from the floor of the box to prevent snakes from escaping or being caught in the door as it returns to the closed position. The barrier has a removable portion to facilitate cleaning and handling of subjects. The inside walls (above the acrylic barrier) and the underside of the moving door are covered with open-cell foam (5 cm thickness), which absorbs some of the noise made by the motor (see below) and the movement of the drawer slides. Three compression springs (one of which is mounted to the stop contact; see below) are glued to the leading edge of the door to dampen the force upon closing.

The rattlebox is automated to open and close automatically at preset intervals using the motor of a remote-controlled toy train (Coastal Express, Scientific Toys, LTD, Chai Wan, Hong Kong), four electrical contacts and a cyclic timer (Canakit, Vancouver, BC, Canada. http://www.canakit.com). Whereas we used a toy train motor to open and close the lid, any radio-controlled motor with forward and reverse will work.

The motor is fixed in a horizontal position with the wheels in contact with a track that is attached to the moving top (Fig. 1). When the motor is engaged in the forward direction the box top is drawn open. The motor is engaged in the forward direction by two

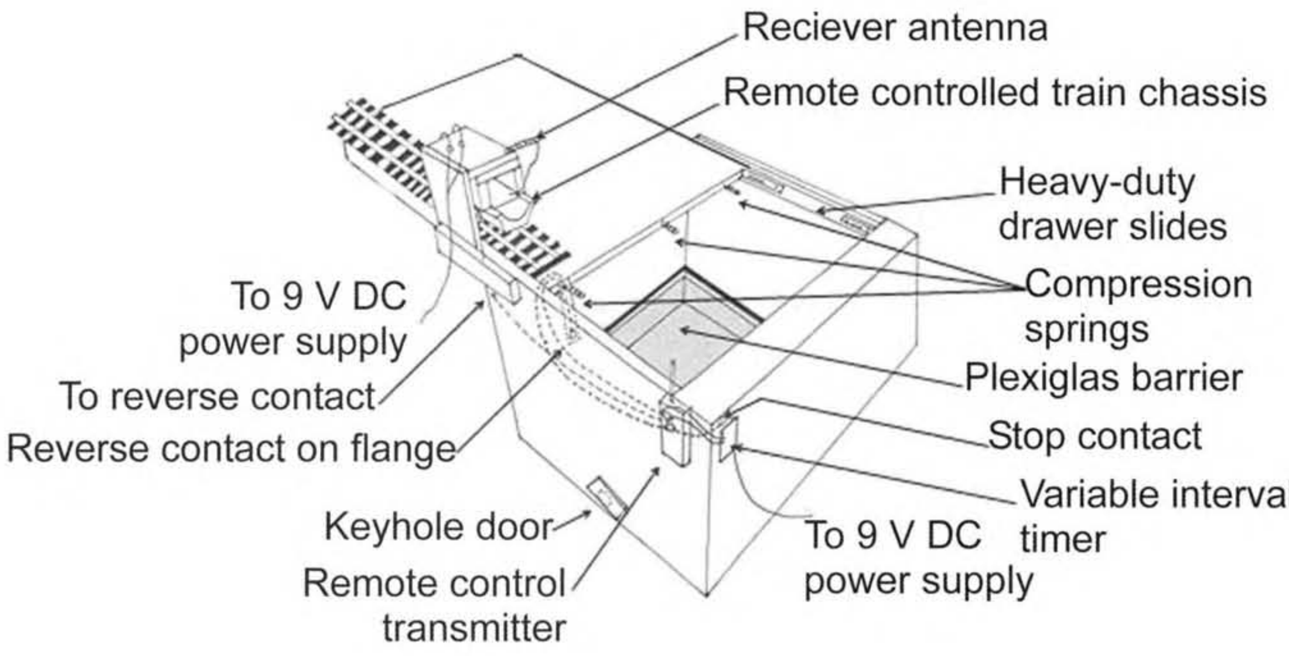

FIG. 1. Schematic representation of the rattlebox. Note the compression spring on the stop contact positioned on the top of the flange bearing the reverse contact. (—) indicates wiring for the forward direction (i.e., open). (– –) indicates wiring for the reverse direction (i.e., closed). (-·-) indicates wiring to stop the motor.

wires that connect the forward button of the remote controller to the normally open and common contacts on the interval timer. To return the top to the closed position, the motor is engaged in the reverse direction by contact made by copper contacts attached to a downward projecting flange affixed to the moving door and the stationary back wall. Contacts are soldered to wires that lead to the reverse button on the circuit board of the remote controller. The motor is stopped at the end of a trial by two additional contacts attached to the forward moving edge of the door and the inside of the front wall of the box. These contacts are soldered to wires that lead to the stop button on the circuit board of the remote controller. A parts list is available from the authors upon request.

A microphone (Earthworks model # M30, Milford, New Hampshire) placed inside the center of the box and pre-amplifier (Earthworks model #1021) outside the box are controlled via a laptop computer by an observer in an adjacent room. Just prior to the beginning of a trial, the observer starts a digital recorder (we used Audio Record Wizard http://www.nowsmart.com/arwizard) and obtains a digital recording of each trial. Between trials each recording is analyzed and the occurrence/non-occurrence of rattling (along with other relevant variables) is recorded.

The rattlebox can be used in the implementation of multiple learning procedures. Below we give a preliminary description of its utility in the study of habituation of the rattle response in Western Diamondback Rattlesnakes. We also outline its potential uses in classical and operant conditioning studies.

Three wild-caught *C. atrox* from Oklahoma were used to test the Rattlebox in a study of habituation of the rattle response. To produce habituation of the rattling response, the top of the box was opened every five minutes (i.e., intertrial interval = 5 min) automatically with the interval timer. For each trial, occurrence or non-occurrence of rattling was determined from playback of digital recordings. Habituation was achieved when a snake failed to rattle for ten consecutive trials, which is a strict criterion for behavioral studies (Ashmead and Davis 1996). Midway between the tenth consecutive no response trial and the eleventh trial, snakes were prodded with a snake hook through the keyhole for ca. 5 sec. This prod served as a dishabituating stimulus. Dishabituation is used to rule out effector fatigue and sensory adaptation as explanations for the observed response decrement to repeated stimulation (Abramson 1994). Two and a half minutes following the presentation of the prod, the lid was opened and the presence or absence of rattling was recorded. The presence of a rattling response during the re-introduction of lid opening is evidence for a learned changed in behavior.

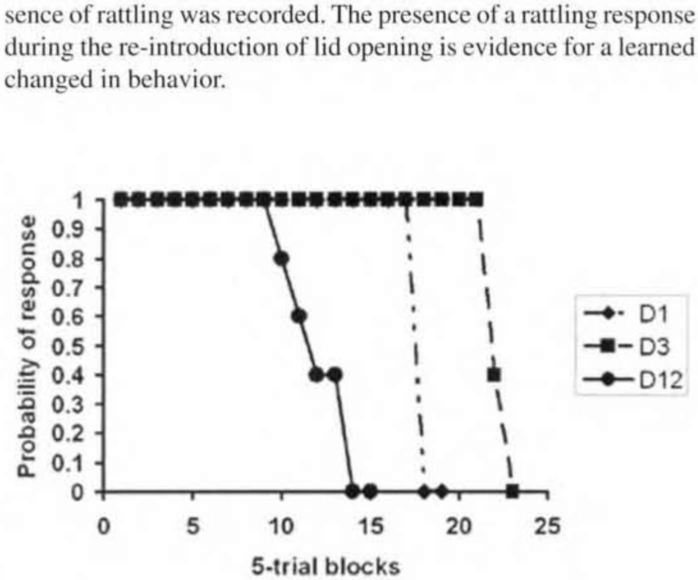

FIG. 2. Habituation of the rattle response by three *Crotalus atrox* tested in the rattlebox. Note the ordinate is in 5-trial blocks and that some symbols overlap.

The habituation curves of the rattle response for subjects D1, D3, and D12 are shown in Fig. 2. Note the high probability of response in the first 50 trials for all three individuals (mean ± SE = 0.99 ± 0.007 for all three individuals combined). Following the dishabituating stimulus, all snakes responded. It is evident that the rattlebox is useful in consistently eliciting a rattle response and in detecting individual differences in rattling behavior.

In addition to habituation, the rattlebox can also be used to study classical conditioning in rattlesnakes. Our laboratory has just begun to test classical conditioning in rattlesnakes in which the opening and closing of the box serves as an aversive unconditioned stimulus. To serve as a conditioned stimulus, we have mounted a 60 W incandescent light on the inside of the box. Temporarily turning on the light serves as a conditioned stimulus.

We have also designed an operant procedure that utilizes the rattlebox. In operant conditioning, a subject's response is reinforced by its consequences. By placing the rattlebox in a cold room and positioning a heat lamp inside wired to a voice-activated relay, each rattle response is rewarded with an increase in ambient temperature. Because rattling typically does not occur spontaneously, it can be shaped by gently prodding the snake with a snake hook through the keyhole.

The results presented here demonstrate the utility of the rattlebox in studies of learning in rattlesnakes. Specifically, Western Diamondback Rattlesnakes repeatedly exposed to an aversive yet harmless stimulus show a learned decrease in rattling. Furthermore, the box is relatively inexpensive and can be built in one day. Extension of the rattlebox to studies of classical and operant conditioning is also easily accomplished. We hope this apparatus will shed light on the perceptual world of rattlesnakes and stimulate further research in the area of learning in snakes.

Acknowledgments.—Development of the apparatus was funded by a grant from the East Texas Herpetological Society to AJP. B. Baker, B. Wilson, and H. Schlothower provided the snakes. N. Birnbaum, N. Faught, and L. Hyde assisted in data collection. An anonymous reviewer made helpful comments on an earlier version of the manuscript.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 36, Number 1 (March 2005).

CAUDATA

AMBYSTOMA OPACUM (Marbled Salamander). **SPERMATOPHORE DEPOSITION.** On 4 Nov 2000, a lone male *Ambystoma opacum* was observed depositing a spermatophore at Ginger's Bay, a small Carolina Bay on the Savannah River Site in Aiken Co., South Carolina. The nearest conspecific, another male, was more than 3 m away during deposition, too great a distance to have influenced the sexually active male by female mimicry (Arnold 1976. Z. Tierpsychol. 42:247–300). Because spermatophore deposition in *A. opacum* occurs very rapidly, with certain individuals achieving as many as 4 depositions in as short as 30 seconds (pers. obs.), there was not sufficient time for another salamander to have interrupted normal courtship with this male, leaving him alone to be observed in an attempt to finish mating. A search of the immediate vicinity yielded no other spermatophores. Previous reports of courtship in *Ambystoma* have emphasized the tendency for males to deposit spermatophores repeatedly, but only in the presence of other courting individuals (e.g., Noble and Brady 1933. Zoologica 11:89-132; McWilliams 1992. Behaviour 121:1–19). These lines of evidence strongly suggest that this individual was engaging in spermatophore deposition in the absence of courtship or influence by either past or present male sexual activity. Males of congeneric species have been reported to deposit in solitude but only after being initially stimulated by mating aggregations or courtship behavior by conspecifics (Anderson 1961. Copeia 1961:132–139; Arnold 1976. *op. cit.*; McWilliams 1992. *op. cit.*). Because males presumably are limited in the number of spermatophores they can produce in a breeding season (Verrell 1986. J. Comp. Psych. 100:291–295; Verrell 1988. J. Herpetol. 22:394–400), selection should strongly favor male mating strategies that result in successful insemination of females. Thus, if isolated spermatophore

HERPETOLOGICAL REVIEW

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2006 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with VISA or MasterCard (account number and expiration date must be provided). Payment should be sent to: Breck Bartholomew, SSAR Membership Office, P.O. Box 58517, Salt Lake City, Utah 84158, USA. Fax: (801) 453-0489; e-mail: ssar@herplit.com.

Future Annual Meetings

2006 — New Orleans, Louisiana, 12–17 July (with ASIH, HL)
2007 — Saint Louis, Missouri (with ASIH, HL)

About Our Cover: *Lyriocephalus scutatus*

This Lyre-headed Dragon (*Lyriocephalus scutatus*) is living in a protected stand of rainforest near Kandy in the uplands of Sri Lanka. The slow-moving agamid is one of a small core of Sri Lankan reptiles that are sometimes referred to as relict endemic taxa.

Sri Lanka (formerly Ceylon) is hailed as having greater biodiversity per unit area than any other Asian country, and most of this lies in the moist southwest and central highlands. Given its close proximity to India, it is hardly surprising that the two countries have much in common. Linked many times since the Miocene (Das 1995. Lyriocephalus 1(1–2):17–20), they share the majority of Sri Lanka's reptile genera and a good many species. Despite this, Sri Lanka is well-endowed with endemics. It seems the moist southwestern regions were subject to the longest periods of isolation, by intervening dry terrain as well as by fluctuating sea levels. More than 80 reptile species, well over half the terrestrial fauna, are endemic to Sri Lanka (de Silva 2001. The Herpetofauna of Sri Lanka. An Historical Overview, Current Status with Checklists. ARROS, Sri Lanka) and most of these are restricted to those high rainfall areas.

The relict endemics include a monophyletic cluster of three agamid genera: *Ceratophora* with five species, and *Cophotis* and *Lyriocephalus* with one species each (Pethiyagoda and Manamendra-Arachchi 1998. J. South Asian Nat. Hist. 3(1):1–50). The group, considered by some as a distinct subfamily, the Lyriocephalinae, features some of the world's most striking lizards. They are characterized by modified rostrums or rostral scales. In some species these form impressive horns, ranging from simple curved structures to large serrated appendages. All are restricted to the southwest or central uplands.

Lyriocephalus scutatus boasts an impressive bulbous hump on the snout and acute bony flanges above the eyes. This 300 mm lizard is usually green, but can change rapidly to brown. Males are largest, with deeper gular sacs and the most protrusive humps. They occur in closed, lowland to sub-montane rainforests, from about 25–1600 m elevation, but have demonstrated a limited degree of tolerance to habitat modification by utilizing well-vegetated home gardens when these abut suitable habitat (Bambaradeniya et al. 1997. Lyriocephalus 3[1]:25–28).

Within their isolated domains the endemic relict agamids have evolved to occupy narrow ecological niches. They now rely on ever diminishing rainforests, threatened by the usual culprits of habitat degradation, deforestation and encroachment by fires, with the resulting fragmentation of populations. They share an island with nearly 20 million people, or around 290 per km^2. Yet *Lyriocephalus scutatus* is one of the lucky ones because it has a reasonably broad distribution through the central uplands and southwest, and its status is currently listed as 'merely' Vulnerable. Many of its horned relatives are restricted to single threatened localities and virtually all are considered to be Endangered to Critically Endangered.

Our cover subject was photographed by Australian herpetologist **Steve Wilson** in a small stand of forest on the outskirts of Gampola. Steve's visit to Sri Lanka is part of an on-going interest in the herpetofauna of tropical islands. His most recent books, *A Complete Guide to Reptiles of Australia*, co-authored with Gerry Swan (New Holland, 2003), and *A Field Guide to Reptiles of Queensland* (New Holland, 2005), are identification guides. His next project, a reptile book for children, aims to instil a sense of wonder into the next generation. This is due for publication in 2006.

Steve used Provia 100 ASA slide film and an Olympus OM2n camera with a 24 mm wide-angle lens. Natural daylight was augmented with a small manual fill flash.

SSAR BUSINESS

Student Travel Awards Silent Auction

The SSAR Student Travel Awards Committee announces the Eleventh Annual Frameable Art Silent Auction to be held at the 2006 SSAR meeting in New Orleans, Louisiana from 12–17 July. Preferred donations include herp-related photos, line drawings, prints, paintings, plates, engravings, or anything frameable, if not already framed. If you are interested in donating an item (tax deductible for U.S. residents), please contact Thomas Eimermacher (e-mail: Thomas.Eimermacher@selu.edu).

SSAR Student Travel Awards Call for Applications

Ten awards of US $200 each are available. An applicant for a travel award must be a student and a member of SSAR, must not have previously received a travel award from SSAR, and must be the first author of a paper or poster to be presented. Application package must include: 1) letter signed by his/her major advisor or department chair that states: he/she is not completely funded for travel from another source; 2) an official copy of the poster or paper abstract to be presented; 3) a self-addressed, stamped envelope. If the research is co-authored, the applicant must also include a letter from his/her advisor stating that the work was primarily the product of the applicant. Qualified applicants are pooled and winners are drawn at random. Students from local meeting site and current members of the SSAR Travel Awards Committee are excluded from applying for a travel award. Applications must be postmarked by 15 April 2006. Award checks will be disbursed at the meeting. Send application package to Dawn S. Wilson, Southwestern Research Station, P.O. Box, 16550, Portal, Arizona 85632, USA or for further information e-mail: dwilson@amnh.org.

SSAR Sustaining Members

SSAR wishes to acknowledge the following Sustaining Members. If you are interested in supporting the Society at this levels (or as a Contributing Member), please contact Breck Bartholomew at the Membership Office (breck@herplit.com).

Ralph Axtell, Lloyd and Mathilde Barr, Bill Barthen, Richard D. Bartlett, Christopher J. Bell, Catherine R. Bevier, Richard W. Blob, Alvin R. Breisch, Sheila E. Tuttle and William S. Brown, Janalee Caldwell, Ulisses Caramaschi, Farley Connelly, Amanda Crnkovic, James Dixon, Howard Evans, John P. Feeney, Stephen Goldberg, James A. Holm, Joseph Hummer, Akihiro Koshikawa, Richard H. Legere, Teresa J. Mayfield, Walter E. Meshaka, Jr., Russell Mittermeier, Paul Moler, John C. Murphy, James Organ, Gretchen E. Padgett-Flohr, William S. Parker, Robert Prescott, Jr., Jack Sites, Jr., Glen Stewart, Laurie Vitt, David Wales, Harlan D. Walley, Hartwell Walsh, Jr.

Journal of Herpetology Changes

On 1 January 2006, the *Journal of Herpetology* will begin to accept submissions via AllenTrack, the web-based manuscript submission and tracking system of Allen Press. AllenTrack will facilitate and expedite editorial manuscript handling, and will make the behind-the-scenes production of the journal more efficient than our current system. Instructions for accessing AllenTrack and submitting manuscripts will be available on the SSAR website (http://www.ssarherps.org). Questions regarding submission of manuscripts via AllenTrack should be directed to Geoff Smith (see below).

Accompanying the implementation of AllenTrack, Geoff Smith will take over as Editor of the *Journal of Herpetology* from Brian Sullivan on 1 January 2006. Brian has served as Editor since 2000. Under Brian's editorship, the journal has seen changes in its format and a drastic reduction in the delay from acceptance to publication of manuscripts (from > 12 months to ≈ 4 months on average). SSAR extends its thanks to Brian for his valued service to the journal and the society.

Geoff has served as an Associate Editor for the *Journal of Herpetology* since 1998. He can be reached at smithg@denison.edu.

2005 Annual Meeting, Tampa, Florida

The 48th annual meeting of SSAR took place from 6-11 July, 2005 at the Marriott Waterside Hotel and Marina in Tampa, Florida. SSAR members once again met with members of the American Elasmobranch Society (AES), the American Society of Ichthyologists and Herpetologists (ASIH), and The Herpetologists' League (HL). The meeting was hosted by the University of South Florida with local organizers Henry Mushinsky, Phillip Motta, and Earl McCoy

A total of 1228 herpetologists and ichthyologists from many countries including Australia, Chile, China, Costa Rica, France, Ireland, New Zealand, and Switzerland attended the meeting. Over half of those present were students! Approximately 690 papers and 310 posters were presented. Six symposia, including one sponsored by SSAR (The Biology of Boas, Pythons, and Related Taxa organized by Bob Henderson, Bob Powell, and Gordon Schuett) were included in the meeting schedule.

A huge thanks are due to Henry Mushinsky and Phil Motta (Co-Chairs) and other members of the Local Committee (especially the graduate students) for all of their hard work. We are grateful to Sharon Brookshire, Jan Hudzicki, and their staff from the Kansas State University Division of Continuing Education for another very smoothly-run meeting

Social Programs and Resolutions

On the evening of 6 July, President Robin Andrews introduced Past-President Janalee Caldwell and Dr. Laurie Vitt (Sam Noble Oklahoma Museum of Natural History, University of Oklahoma) who jointly gave this year's SSAR President's Travelogue "*From the Amazon to the Cerrado: Reptiles and Amphibians of Brazil.*" Between the two of them, they have over 50 years of experience in the neotropics and, as anyone who saw Jan and Laurie's photographic exhibition in the Sam Noble Museum at the 2004 JMIH could have predicted, we were treated to an amazing slide show of parts of Brazil of which most of us only dream.

Henry Mushinsky and Phil Motta opened the Plenary Session on 7 July and welcomed us to Tampa. In addition to providing general information about the meeting and meeting venue, both Henry and Phil warned us of sharks, lightning, and Ybor City. Dr. Renu Khator (Provost and Vice President of Academic Affairs, University of South Florida) also welcomed us to Tampa (and warned us yet again about Ybor City), invited us to visit the University, and then spoke about many of the challenges she saw facing higher education.

These welcomes were followed by well-received presentations from Patrick Gregory (Past-President, ASIH), Roy McDiarmid (Distinguished Herpetologist, HL and President-Elect, SSAR), and Sonja Fordham (The Ocean Conservancy). As usual, the Annual Group Photograph followed the morning Plenary Session and paper sessions began after lunch. The General Reception was held that evening at the Florida Aquarium, a short walk up the road from the meeting venue.

In a repeat of last year, where tornado warnings drove the Annual Picnic indoors, weather once again, this time in the form of Hurricane Dennis, resulted in this year's picnic being an indoor event. It lacked some of the anticipated ambience of the planned venue (the Lowry Park Zoo), however a good time was had by all.

Over $5,300 was raised at the Annual SSAR/HL Live Auction held on Sunday evening. SSAR uses these funds to support Student Travel Awards. Thanks to David Green for his auctioneering skills, to Ron Javitch for his very generous bidding, and to Stan Trauth who donated a Hellbender t-shirt on behalf of the Cryptobranchid Interest Group. The t-shirt was signed by the speakers at a recent Hellbender conference and was auctioned for $100.

The Annual Banquet was held in the Marriott Hotel on 11 July with Larry Page (prior Past-President, ASHI) serving as the Master of Ceremonies. Past-Presidents of ASIH, SSAR, HL, and AES in attendance at the banquet were acknowledged. There was one Past-President over age 80 and several over age 70. In a remark that now appears prescient (and at the time provoked much laughter), Henry Mushinsky issued Bob Cashner (Chair, Local Organizing Committee for the 2006 JMIH in New Orleans) with a challenge to beat the tornados that threatened the 2004 JMIH and Hurricane Dennis that threatened the 2005 JMIH.

A number of awards were presented including *both* the Robert K. Johnson and Henry S. Fitch Awards to Dr. Margaret Stewart. The Johnson Award is to honor members of ASIH who have provided outstanding service to the society and the Fitch Award honors an individual for long-term excellence in the study of amphibian and/or reptile biology. Dr. Stewart received her Ph.D. from Cornell University and joined the Department of Biological Sciences at the State University of New York, Albany in 1956. She is widely-known for her work on population, behavior, and community ecology of amphibians especially *Eleutherodactylus coqui* in Puerto Rico. Meg is author or coauthor of over 65 scientific papers and reviews. She has supervised 16 Ph.D. or Master's students and over 40 undergraduate theses as well serving as an important mentor to many in the herpetological community.

Meg has served both SSAR and ASIH. She was President of SSAR in 1979, has served on and chaired the Nominating Com-

SSAR President Robin Andrews congratulating Dr. Meg Stewart, the 2005 recipient of the Robert K. Johnson and Henry S. Fitch Awards. (M. Preest)

mittee, chaired the Kennedy Student Award Committee, served on the editorial board of Journal of Herpetology, and has been part of the Long Range Planning Committee. For ASIH, Meg was President in 1996 and Historian for a number of years. She has also been active with the World Congress of Herpetology. These awards to Meg were greeted with loud applause from the Banquet attendees. Meg looked pleasantly stunned to receive the first award and then doubly stunned to receive the second. SSAR congratulates Meg for this well-deserved recognition.

The following SSAR resolutions, prepared by Richard Wassersug (SSAR Resolutions Chair), were read:

Resolution on Outgoing SSAR Officers, Editors, and Others:
Whereas, the following individuals have given freely of their time, energy, and expertise to SSAR, and,
Whereas, because of their hard work and dedication, SSAR programs, projects, and goals have been advanced, and,
Whereas, SSAR is dependent on the generosity and tremendous efforts of its members and is grateful for their willingness to serve,
Therefore be it resolved that the Society for the Study of Amphibians and Reptiles offers its gratitude and sincere thanks for jobs well done to the following individuals: Joe Mendelson, Board of Directors; Gabriela Parra Olea, Board of Directors; Robert Powell, Editor, *CAAR*; Steve Corn, Editor, *Herpetological Conservation*; Brad Hollingsworth, Associate Editor, *Herpetological Review*; Daryl Karns, Associate Editor, *Herpetological Review*; Brian Bowen, Associate Editor, *Herpetological Review*; Ruston Hartdegen, Herpetological Husbandry Section Editor, *Herpetological Review*; Eli Greenbaum, Current Research Section Editor, *Herpetological Review*; Linda Ford, Resolutions Committee Chair; Dennis Desmond, SSAR Webmaster; Zack Walker, SSAR Webmaster; Ruston Hartdegen, Coordinator, *Relationships with Herpetologists at Zoological Parks Committee*; James Murphy, member, *Relationships with Herpetologists at Zoological Parks Committee*.

Resolution on 5th World Congress of Herpetology:
Whereas, the organizers of the 5th World Congress of Herpetology (Stellenbosch, South Africa) put on a stellar conference in terms of both its scientific content and stimulating, pleasant atmosphere, and,
Whereas, this contribution to herpetology was appreciated by visitors from all around the world,
Therefore be it resolved that the SSAR congratulates the World Congress for such a successful meeting and looks forward to similar successful World Congresses in the future.

The following joint society resolutions were read by Adam Summers (Chair, ASIH Resolutions Committee):

Joint Resolution Thanking the Local Committee:
Whereas the Tampa meeting was a great success, and
Whereas the local color was interesting, tasty, and, in Ybor city even titillating,
Therefore be it resolved that the society heartily and sincerely thanks Phil Motta and Henry Mushinsky for their hard work as local committee chairs.

Whereas 20 years ago Henry Mushinsky, then a callow assistant professor hosted a meeting of SSAR and HL in Tampa, and
Whereas the information packet for that meeting contained a list, complete with extensive reviews, of the local topless bars,
Therefore be it resolved that the society recognizes Henry for having matured and mellowed into a politically correct, tactful, and tasteful full professor.

Whereas the society recognizes that a substantial portion ... some would say all, of the work associated with the meeting was accomplished by the many students associated with the Motta, McCoy and Mushinsky labs,
Therefore be it resolved that the society recognizes and thanks them for their efforts.

Joint Resolution Concerning Storms and Floridians:
Whereas, the timing of the Joint Meetings of Ichthyologists and Herpetologists coincides with the tropical hurricane season, and
Whereas, Hurricane Dennis caused some anxious moments for participants at this year's meeting, altering plans for yet another outdoor picnic, preventing most participants from venturing from the meeting hotel for two full days, overwhelming hotel's restaurants and bars at the hotel, and stranding those brave enough to dine elsewhere, but causing no harm to anyone, and
Whereas, Floridians have had to deal with far too many Hurricanes in the past few years, with many people losing their life and homes or were otherwise massively inconvenienced, and
Whereas, the Florida Keys and Panhandle had to endure the wrath of Hurricane Dennis,
Therefore be it resolved that participants at the Joint Meetings of Ichthyologists and Herpetologists send well wishes to Floridians affected by Hurricane Dennis and previous hurricanes, and hope that the state will be spared from future hurricanes.

Joint Resolution Thanking Student Attendees:
Whereas these meetings are greatly enhanced, and even defined by the contributions of our student members, and
Whereas student members made up 60% of our total attendance, and
Whereas students rather than professors brought the vast majority

of the captured herps to the hotel bar,
Therefore be it resolved that the society thanks the students for their presence and reminds them to attend business meeting and volunteer their service to the society.

The Banquet closed with thanks from Larry Page to the Local Committee and Conference Organizers and a warm invitation from Bob Cashner to attend to 2006 Joint Meeting in New Orleans, Louisiana (12–17 July).

Board Meeting and Business Meeting Summaries

Society President Robin Andrews called the Annual SSAR Board Meeting to order at 0805 h on 6 July 2005 in the Marriot Waterside Hotel and Marina, Tampa, Florida. In attendance were 11 members of the Board of Directors and 13 Editors, Committee Chairs, or members of the Society. Minutes of the 2004 Board of Directors Meeting (Norman, Oklahoma) were approved.

In her first 6 months in office, President Andrews, with the unanimous support of the Board, signed an agreement that made SSAR a participant in JSTOR. The Society will receive several thousand dollars in royalties annually. President Andrews appointed Clay Garrett as chair of the Relations with Herpetologists at Zoological Parks Committee and Alan Savitzky as chair of the Committee that will organize SSAR's 50^{th} Anniversary celebration in 2007 (Robert Aldridge, Breck Bartholomew, Janalee Caldwell, Jonathan Losos, Henry Mushinsky, and Kirsten Nicholson, members). She recommended that the President's Challenge Fund be used to support the activities of this Committee. She wrote letters of congratulation to the 2005 recipient of the Dean E. Metter Award (Matthew Chatfield), to the winner and runner-up of the 2005 Kennedy Student Award (Cameron Stevens and Caren Goldberg respectively), and to Janalee Caldwell, Ellen Censky, and William Matthews for hosting the 2004 JMIH in Norman. Janalee Caldwell and Laurie Vitt were invited to present the President's Travelogue at the 2005 JMIH.

Past-President Caldwell appointed Zachary Walker to replace Dennis Desmond as SSAR webmaster and worked closely with Zack and Dennis during the transition. She also appointed Anne Maglia to chair the new Web Oversight Committee (Gad Perry and Lisa Beldon, members) and Catherine Bevier to chair the Herpetological Education Committee (HEC, a joint SSAR/HL committee; Taylor Edwards, Steve Mullin, Greg Watkins-Colwell, Ruston Hartdegen, Dave Hardy members). Additional information about this committee is available on the SSAR website. SSAR has many important documents currently in the possession of past founders, officers, and members. George Pisani has agreed to serve as the society archivist and will work with Kraig Adler and President Andrews.

During the 2004 JMIH, Janalee Caldwell (along with various officers and editors of the three herpetological societies) attended a meeting with Allen Press to discuss aspects of BioOne and the future of the Society's journals.

Following the Business Meeting in Norman, President Caldwell turned over the SSAR gavel to Robin Andrews.

Treasurer, Theodora Pinou reported that the Society made a profit of \$34,377 for calendar year 2004; \$5,563 in operating income, \$2,974 in donations, and \$16,196 of realized investment income. Dora reported that the society is currently in a sound financial position and recommended implementing a plan to ensure long-term financial security. The Long-Range Planning Committee will be consulted regarding engaging the services of a professional portfolio manager to offer investment advice to the Society. Dora

Participants in the SSAR-sponsored symposium "The Biology of Boas, Pythons, and Related Taxa." Photograph by M. Preest.

and President Andrews will discuss the funding of the Henri Seibert and Kennedy Awards and contact the Planning Committee with suggestions.

The move of the Publications Library from St Louis University, Missouri to Salt Lake City, Utah was completed by late 2004 at a cost of $14,220.

The decline in membership numbers noted in recent annual reports continues this year. There was ongoing discussion of the benefits of SSAR membership in the face of increased reliance on BioOne for access to society journals. A penalty fee of $10 for late membership renewal was recently imposed. Although this penalty has not been enforced, $1,170 has been raised voluntarily. This will be used to cover the extra costs of postage.

Dora provided an accounting of various Book Initiate Funds (e.g. Bailey Endowment Fund, Gordon Fund, etc.) and Student Award Funds (e.g. Dean Metter Memorial Award, Minton Endowment Fund, etc.). The Board has not allocated funds for the International Cooperation Project Fund since it was established a number of years ago. President Andrews recommended that the HEC use this fund to update the list of research grants published on the Society website (this list was generated by Janalee Caldwell and Rafael de Sá). Dues forms will continue to include a box where members can indicate whether they wish to make a contribution to the International Cooperation Project and contributors will be acknowledged on the website.

There was discussion of a proposal to initiate a Middle School Special Award in Herpetology (provide $50 per state science fair). The Board felt that support of our graduate student members should take precedence over support of younger students. It was suggested that a certificate of acknowledgement or an SSAR publication might be suitable for Middle School students. The logistics of such an undertaking will be substantial. The HEC will consider this suggestion.

Currently, $1000/yr is budgeted to cover Society website expenses. The cost of hosting the website is expected remain at approximately $180/yr. Additional funds could be used to update the site, add images, provide sample PDF files of chapters from SSAR publications, etc.

Among her duties in the past year, Secretary Marion Preest reported that she wrote a summary of the 2004 Annual Meeting, compiled the 2005 Annual Report, and prepared agendas for the Board and Business Meetings at the 2005 Annual Meeting. She also worked closely with Kirsten Nicholson (Chair, Nominations Committee) prior to the election held in 2004. Marion communicated with the nominees and reported the results of the election in *Herpetological Review*.

Breck Bartholomew (Publication's Secretary) reported that income from sales of the Society's publications totaled $37,248. He distributed a list of recent Society publications to those in attendance at the Board meeting. Material is still being counted and organized following the move of the Publications Library to Salt Lake City. Breck advertised the recent facsimile *Les Tortues de l'Indochine* using a postcard mailing. The net income generated suggested that this may be a profitable way of advertising Society publications. Dealing with returned journals involves a considerable expense for the Publications Office. The Web Oversight Committee will investigate the possibility of including a change of address function on the website. There was discussion of the initiation of a "junior membership category" for high schools and middle schools. The school might be charged an individual rate rather than an institution rate. The HEC will consider this.

Lunch break for Julian Lee, Bobby Espinoza, Linda Ford, and Jose Rosado. (M. Preest)

Robert Powell, Editor of *Catalogue of American Amphibians and Reptiles* (*CAAR*), reported on the status of this publication effort. Bob has stepped down as editor (although he continues to help in an advisory capacity) and Andy Price has assumed the role of editor. Gregory Watkins-Colwell has become an Associate Editor and Twan Leenders was appointed as section editor for Anura. Bob noted that the 2004 contributions to *CAAR* consisted of 20 accounts (Nos. 781–800; 3 salamander, 3 frog, 1 turtle, 10 lizard, and 3 snake accounts plus an index to accounts 601-800) for a total of 76 printed pages. Color plates were included in 19 of the accounts. Andy Price reports that the 2005 subscription is tentatively scheduled for publication on June 30 (20 accounts), and he has plans for another 20 accounts for 2006. Andy indicated that he may consider other printers to see if savings can be made. The *CAAR* index on the website needs updating. Breck Bartholomew will send a copy of *CAAR* to all members along with a catalogue of SSAR publications. Bob reported that he faces a continual struggle to receive an adequate number of accounts and that the accounts he has received recently have not been geographically balanced (there is a paucity of accounts on Central and South American taxa).

Kraig Adler (Editor) reported on the publication activities of *Contributions to Herpetology*. No books were published in 2004. "*Biology of the Reptilia*, Volume 20 (Morphology)," edited by Carl Gans and Abbot Gaunt is anticipated for December 2005. Formatting will begin shortly on "*Tasks and Problems Studying the Life of Reptiles in Zoos*," by Hans-Günter Petzold and, although the final manuscript has not yet been submitted, much preliminary work has been done on the color plates of "*Field Guide to Amphibians and Reptiles of the West Indies*," by S. Blair Hedges. Future publications will include "*Herpetological Time Travel Through the Zoo and Aquarium World*," by James B. Murphy, and "*Lizards of Southern Africa*," edited by William R. Branch and Aaron Bauer.

Editor of *Facsimile Reprints in Herpetology*, Aaron Bauer, reported that two new facsimiles were published in 2005; "*Les Tortues de l'Indochine*" by René Bourret and "*The Herpetologi-*

Brian Crother and Henry Mushinsky at the SSAR/HL live auction. (M. Preest)

cal Contributions of Sir Andrew Smith" with a biography, concordance of names and annotated bibliography by William R. Branch and Aaron M. Bauer. This last publication was included in the meeting bags of delegates at the recent World Congress of Herpetology in South Africa as a commemoration of the meeting and an SSAR promotion. Planned for publication in early 2006 is "*The Herpetological Contributions of Mario Giancinto Peracca*," edited by Franco Andreone and Elena Gavetti (with an English translation of the introduction) and possible for early 2007 is "*The Herpetological Contributions of John Edward Gray.*" Other titles that are under consideration for future facsimiles include the collected works of Lönnberg and Andersson, "*Zur Entwicklungsgeschichte und Anatomie der Ceylonesischen Blindwuehle Ichthyophis glutinosus*" by Sarasin and Sarasin, and "*The Fossil Turtles of North America*" by O.P. Hay. *Herpetological Circulars* Editor, John Moriarty, reported that HC 33, "*Johann von Fischer and His Chameleons: The History of the Common Chameleon*" will be published in late 2005. It will be 96 pages with a full color cover. A grant from the Atherton Seidell Endowment Fund of the Smithsonian Institution has been requested to cover printing costs. "*A Review of Marking Techniques for Amphibians and Reptiles*" is anticipated in early 2006 and "*Synopsis of Helminths Endoparasitic in Snakes of the United States and Canada*" is planned for late 2006.

Former Editor, Steve Corn reported that Volume 2 in *Herpetological Conservation*, "*Ecology, Conservation, and Status of Reptiles in Canada*," is expected in late 2005. Robin Jung and Joe Mitchell, current Co-Editors of *Herpetological Conservation* reported that they have received 28 of the 55 proposed manuscripts for Volume 3 "*Urban Herpetology: Ecology, Conservation and Management of Amphibians and Reptiles in Urban and Suburban Environments.*" They expect reviews of all manuscripts to be completed by August 2005. Joe indicated that there has been much interest in this publication and that outside funding is being sought.

Herpetological Review Editor, Robert Hansen reported a 6% increase in the number of pages in *Herpetological Review* Volume 35 compared with Volume 34 and a 69% increase since 1999. He expects Volume 36 to be approximately the same size as Volume 35. The time lag for publication ranges from 3–15 months. Most manuscripts are submitted and handled electronically. Greater scrutiny of submitted manuscripts by editorial staff has resulted in an increase in the rejection rate. The SSAR author assistance program continues to be used. Brad Hollingsworth (Associate Editor), Daryl Karns (Associate Editor), Ruston Hartdegen (Section Editor), and Eli Greenbaum (Section Editor) have resigned. New appointments include Steve Johnson as Associate Editor, Michael Burger and Michele Johnson as Section Editors, and Barbara Banbury and Michael Jorgenson as Copy Editors.

Journal of Herpetology Editor, Brian Sullivan submitted a report indicating that the number of submissions in 2004 was similar to that in the last several years. The rejection rate in 2004 was comparable with that in recent years (50–60%). In the first 3 months of 2005, 76 manuscripts were received. Use of AllenTrack will begin in 2006 and is expected to reduce the time involved in review and publication of manuscripts. Peter Ducey and Andrew Price have joined the staff as Associate Editors. In 2006 Geoff Smith will assume the position of Editor and Brian will step down. A replacement for Bill Parker (Managing Editor) is being sought.

The Board received reports from all standing committees. Stephen Richter (Chair) reported that the Conservation Committee has updated its material on the SSAR website. They have discussed updating the state conservation links on the website, developing associations with other conservation organizations, and developing education-oriented goals, potentially in collaboration with the Herpetological Education Committee.

The screening committee for the Dean Metter Memorial Award (Joseph Beatty [Chair], Anne Maglia, and Brian Miller) received eight proposals for the third Dean E. Metter Award. An award was made to Matthew W.H. Chatfield for his proposal "Hybrid Zone Dynamics Between Two Species of Salamanders in the Genus *Plethodon*."

Erik Wild, Chair of the Grants in Herpetology Committee received fifty-seven proposals in 2005 and the committee made awards of $500 in each of seven categories (Conservation, Field Research, Laboratory Research, Herpetological Education, Travel, International, Bibliographic Research). Erik expressed satisfaction in changes implemented last year in the application process.

Marion Preest (Chair, Henri Seibert Awards Committee) reported that five awards were made at the 2004 Norman meeting. In 2005, the Systematics category, which has recently attracted few participants, was combined with the Evolution category.

The recently-formed Herpetological Education Committee (a joint SSAR/HL committee, Catherine Bevier, Chair) has taken on the task of setting up a "herp hotline" (on the SSAR and HL websites) to facilitate addressing questions regarding herps from the academic and hobbyist communities. In the future, this committee will update the "Careers and Jobs in Herpetology" webpage.

Chair of the Kennedy Student Award Committee, Bob Gatten reported that the winner of the 2005 Kennedy Student Award is Cameron Stevens for his paper:

Stevens, C. E., and C. A. Paszkowski. 2004. Using chorus-size ranks from call surveys to estimate reproductive activity of the

wood frog (*Rana sylvatica*). Journal of Herpetology 38:404-410.

This year this committee also chose Caren Goldberg as a runner up:

Goldberg, C. and C. Schwalbe. 2004. Habitat use and spatial structure of a barking frog (*Eleutherodactylus augusti*) population in southeastern Arizona. Journal of Herpetology 38:305-312.

Henry Mushinsky (SSAR Rep, Meeting Planning Committee) reported on the development of plans for upcoming JMIH meeting (anticipated sites - 2006, New Orleans; 2007, Saint Louis; 2008 Montreal; 2009 Long Beach). Financial concerns necessitated changing the venue of the 2007 meeting from Ithaca to Saint Louis. The 2008 meeting was originally proposed as a joint meeting with the World Congress of Herpetology (WCH) but the WCH will be moved to another, as yet undetermined, venue. The committee is trying to alternate meeting venues across the United States and states that it is open to meeting in other countries.

There was discussion of the following proposals from the Meeting Planning Committee:

1. Limit the total number of oral presentations to 700
2. Set new deadlines and change procedures for the approval of symposia
3. Limit the total number of symposia to eight
4. Establish a procedure for workshops
5. Establish a plan to share costs/benefits of JMIH

The Board approved proposals 1 and 2 at the meeting and the remaining proposals were approved electronically by the majority of the Board following the meeting. The first 700 abstracts received for oral presentations at meetings will be accepted and the remainder will be accepted as posters. Currently there is no plan to limit the number of posters. The Board was informed that the new limit of 700 would not apply if there is a joint meeting of JMIH and WCH. The deadline for approval of symposia proposals by the respective societies will now become 31 March of the preceding year (i.e. approximately 16 mo prior to the symposia being held). This will allow the Meeting Planning Committee to better coordinate the symposia when they meet in April. Societies will submit a ranked list of symposia to the Meeting Planning Committee. An attempt will be made to balance symposia between societies and in terms of topics, taxa, etc.

Strong support for planning a joint meeting with WCH was voiced by virtually all attendees at the Board meeting. There was discussion of whether SSAR should always participate in a World Congress regardless of where the meeting is held or whether SSAR should always participate in a World Congress when the meeting is held in the Americas. No decisions were made. In reference to the proposal above regarding a plan to share the costs and benefits of JMIH, the Treasurer requested that she be provided with a breakdown of costs of recent joint meetings.

In 2005, the Nominations Committee (Kirsten Nicholson, Chair) presented a slate of eight nominees for four Directors positions (three regular, one non-US) and two nominees for the position of President-Elect. Dora Pinou (current Treasurer) and Marion Preest (current Secretary) agreed to serve additional terms. No election will be held in 2005. A new procedure will be implemented in 2006 to allow the Elector to track voters and to ensure confidentiality of votes.

Resolutions were read at the 2003 meeting in Norman (Linda Ford, Chair, Resolutions Committee) thanking retiring members of SSAR for their service and acknowledging Rafe Brown for his presentation of the SSAR President's Travelogue and the SSAR Conservation Committee for bringing recognition to the society (see *Herp. Review* 35(4): 306-308). Richard Wassersug has replaced Linda Ford as chair of this committee.

Brian Crother (Chair, Standard English and Scientific Names Committee) reported that an update of the names list was published in *Herp. Review* 34:196-203. Although successful in standardizing usage of most names, the list has also generated some controversy. The committee had anticipated beginning work on the next volume in 2004, but this was decided to be too soon. Brian commended the members of the committee for their service.

Twenty-seven applications were received for the Student Travel Award and ten awards ($200 each) were presented by Dawn Wilson at the Business Meeting in Norman.

Anne Maglia (Chair, Web Oversight Committee) reported that Dennis Desmond resigned as webmaster and was replaced by Zachary Walker. New features of the site include the ability to pay membership dues online, html alternatives for pdf document downloads, and access to pages of herpetological FAQ's. Formatting has been standardized and, in consultation with the Secretary and appropriate committee chairs, listings of committee memberships have been updated. The web domain name "ssarherps.org" has been renewed.

Elector, Maureen Kearney reported the results of an election held in Fall 2004: President-Elect (Roy McDiarmid) and four Board members, class of 2008 (Rafe Brown, Meredith Mahoney, Jim McGuire – Regular Members; Rick Shine – non-US Member). Theodora Pinou and Marion Preest were reelected as Treasurer and Secretary respectively.

In his report, Clay Garrett (Chair) presented the mission statement, general goals, and recent activity of the Relations with Herpetologists at Zoological Parks Committee. Clay presented a paper (Herpetological Research in Zoos: A Contemporary Assessment; In press, *Herpetological Review*) at the annual AZA Taxon Advisory Group Meetings in New Orleans, LA, stressing the importance of collaboration among zoo curators and between zoo and academic colleagues. He also gave an overview of the upcoming SSAR Relations with Herpetologists at Zoological Parks Committee web page and forum. The committee will attempt to recruit international herpetologists to add to its membership. Specific goals for 2005 include development of a database of papers resulting from zoo/academic collaboration, discussion of a symposium on zoo/academic research at future JMIH, and completion of a Committee web page with an interactive component to facilitate dialogue and the exchange of ideas between the zoo and academic communities. The web forum will require a one-time fee to be covered by the Ft. Worth Zoo. Entry to the forum will be restricted and users will require a username and password.

Clay presented some statistics regarding use of the SSAR website; the site appears high on a Google search, approximately 90% of the visitors to the site are from the United States, approximately 80% of the visitors remain on the site for less than 30 seconds, and 85% remain for less than 2 minutes. There was some discussion of what could be done to increase the number of visitors and the amount of time visitors spend on the site. It was suggested that adding search terms in languages other than English

might have an effect.

Al Savitzky (SSAR Representative to the American Institute of Biological Sciences, AIBS) submitted a report detailing his activities. He attended the 2005 AIBS annual meeting in Washington, DC. An informational brochure on the organization was published this year and is available at www.aibs.org/about-aibs/resources/AIBS_brochure.pdf. The major strength of AIBS, from the perspective of our Society, is its involvement in educational issues and science policy, including especially federal research funding and conservation policy. Al noted that the AIBS Outstanding Service Award was presented to Jay Savage for his contributions to organismal biology and ecology and his work with the Organization for Tropical Studies.

AIBS sponsored a series of presentations on "Evolution and the Environment" at the Fall, 2004 meeting of the National Association of Biology Teachers. The Education Office has been heavily involved with two issues, workforce diversity and the teaching of evolution. AIBS also sponsors an education specialist through a subcontract with the National Evolutionary Synthesis Center (NESCENT), an NSF-funded inter-institutional project headquartered in Durham, NC. In addition to the educational aspects of the program, SSAR members may be interested in the varied research opportunities available through NESCENT (www.nescent.org/). AIBS also manages the website ActionBioscience.org (www.actionbioscience.org/), which was founded by a private philanthropist and later transferred to AIBS. The site contains writings on a wide range of biological topics, in both English and Spanish. A new category of membership for academic units (such as biology departments) has been announced. Efforts to establish NEON (National Ecological Observatory Network, www.neoninc.org/) continue with a $6M grant from NSF. AIBS plans to request funding from Congress to begin building the network in 2007.

Following the AIBS meeting, a session was devoted to discussion of BioOne and Open Access publishing. BioOne has shifted its business model from one of providing supplemental income to one of providing replacement income to make up for anticipated future losses of library subscriptions for print journals. BioOne continues to enjoy the support of the academic library community and subscriptions to BioOne are increasing, especially overseas, where the collection has been marketed actively. BioOne entered into an agreement with JSTOR whereby "legacy content" (back issues) of journals published by BioOne publishers will, with the permission of the publisher, be carried by JSTOR. Furthermore, BioOne will establish a "moving wall" by which the most recent several years of each publication will be carried by BioOne and the oldest BioOne volume will be transferred to JSTOR for archiving.

Open Access (OA) publishing involves immediate free access to published content, posting in an open archive, and no copyright restrictions on re-use of materials. This raises obvious concerns for both nonprofit (such as SSAR) and for-profit publishers. The concept of OA publishing received a major boost when the Director of NIH, Elias Zerhouni, proposed that all NIH-funded research be made open access. That policy was adopted by Congress this Spring. Technically, the policy only "recommends" that the research be made available through OA, but the biomedical community views it as a *de facto* requirement. Despite many flaws and strong resistance from the scientific community, the NIH argument that publicly funded work should be available free to all users is popular with the public and politicians, and there is concern that the NIH lead may be followed by other agencies. Reportedly, NSF is not interested in promoting OA, but it still could be mandated to do so. Steep increases in the costs of journal subscriptions, together with the perceived need of the public to have access to medical research results, has fueled the NIH policy on OA. Rather than subscribers or readers paying, the most common model for OA is "author-pays," with an estimated cost to authors of several thousand dollars per submission. In the NIH model, the presumption is that the funding agency will absorb these costs through their inclusion in grants, but in organismal biology and ecology an author-pays model could be catastrophic. Unfunded, modestly funded, and overseas researchers would be greatly disadvantaged by such a system. Interested members of SSAR are directed to materials from the recent AIBS meeting on OA, which are to be posted on the AIBS website (www.aibs.org) by the end of May.

Al summarized a presentation on the economics of publishing science, technology, and medicine journals (octavia.zoology.washington.edu/publishing/). In ecology, the price per page for library subscriptions to nonprofit journals averaged $0.19, versus $1.19 for for-profit publishers. More surprisingly, the oft-heard argument that the higher priced commercial journals are "better" — i.e., have higher impact factors, etc. — is in fact untrue for the general classes of nonprofit and for-profit journals. Based on ISI impact factors, five of the top six journals in ecology are published by nonprofit publishers.

Dick Durtsche (Symposium Coordinator) received a proposal from Peter Paton and David Scott for SSAR to sponsor a half-day symposium, "Amphibian and Reptile Use of Golf Courses" at the 2006 Annual Meeting in New Orleans. The proposal was sent to two reviewers, both of whom returned positive recommendations. Sponsorship is being provided by the USGA/NFWF Wildlife Links program. A motion to accept this proposal was made and approved by Board members.

The SSAR 2006 budget was approved. There being no further business, the meeting was adjourned at 1455 h.

The Annual SSAR Business Meeting was called to order by President Andrews at 1705 h on 9 July. Approximately 38 SSAR members were in attendance. President Andrews summarized business dealt with at the Board Meeting on 6 July. Winners of the 2005 Kennedy Award, Seibert Student Awards, Grants in Herpetology Awards and Student Travel Awards were announced. Al Savitzky lead a brief discussion of some issues related to BioOne and Open Access publishing. The meeting was adjourned at 1800 hrs.

—Respectfully submitted by
Marion Preest, SSAR Secretary

NEWSNOTES

Slowinski Award Announced for 2005

The Center for North American Herpetology is pleased to announce that the recipient of The Joseph B. Slowinski Award for Excellence in Snake Systematics for 2005 is Zoltan Nagy, of the Institute of Pharmacy and Molecular Biotechnology, University of Heidelberg, Germany.

On 12 September 2001, the world lost one of its premier biologists, a loss that went virtually unnoticed in the wake of the tragedy that befell the United States the previous day. Joseph Bruno Slowinski, the 39-year old curator of amphibians, turtles, reptiles, and crocodilians at the California Academy of Sciences in San Francisco, died in the jungles of Burma from the bite of a venomous snake. Joe was bitten on 11 September and, despite heroic efforts to save his life by expedition companions and colleagues, succumbed to the effects of the bite the next day. Eventually, the world took notice, and numerous media outlets across the nation and throughout the world chronicled Joe Slowinski's exemplary career, cut so tragically short.

A distinguished committee, comprised of Frank Burbrink (City University of New York, Staten Island), Brian Crother (committee chair, Southeastern Louisiana University, Hammond), and Robin Lawson (California Academy of Sciences, San Francisco), have deemed the paper entitled "Molecular Systematics of Racers, Whipsnakes and Relatives (Reptilia: Colubridae) Using Mitochondrial and Nuclear Markers" (2004. Journal of Zoological Systematics and Evolutionary Research), as the most distinguished paper on snake systematics to appear worldwide during 2004. The paper was co-authored by Robin Lawson, Ulrich Joger, and Michael Wink.

As senior author of the paper, Zoltan Nagy becomes the third recipient of The Slowinski Award, and will receive a check from The Center for North American Herpetology for US $500 along with a commemorative memento in recognition of his achievement.

Adler Completes Term as Vice Provost at Cornell University

Kraig Adler, Professor of Biology at Cornell University, ended his seven-year term as Cornell's Vice Provost for Life Sciences in June. In this newly created post, he had responsibility for the university's $650-million New Life Sciences Initiative, which involves more than 500 professorial faculty. The objective of this initiative is to integrate the life sciences with the physical, engineering, and computational sciences without compromise to Cornell's traditional strengths in organismal biology.

During Adler's tenure as vice provost, 55 new life science faculty were appointed in six colleges and $350 million in life science building projects begun. He also oversaw the Ithaca-campus portions of the Tri-Institutional Research Program, a $160-million cooperative project with Weill Cornell Medical College, Rockefeller University, and Memorial Sloan-Kettering Cancer Center in New York City.

Adler now returns full-time to this faculty position in the Department of Neurobiology and Behavior when he will teach and complete several books in progress. He joined the Cornell faculty in 1972 and has served as chair of his department on two occasions. Previously he had been on the faculty of the University of Notre Dame after completing his doctorate at The University of Michigan in 1968.

Call for Symposium Proposals for the 2007 Herpetologists' League Meeting

The Herpetologists' League sponsors thematic symposia for its annual meetings. Any League member may submit a proposal for a symposium for the upcoming meeting by sending a proposal application to the chair of the Symposium Committee. Official sponsorship by the HL allows for the scheduling and announcement of the symposium in the meeting program and registration materials. In addition, a small amount of financial support (a maximum of $ 2000) is available to support sponsored symposia. Sponsorship by the HL does not guarantee financial support and symposia may be sponsored in name only or funded at a level lower than requested by the applicants.

Interested persons should contact Rafael de Sá, Chair HL Symposium Committee (e-mail: rdesa@richmond.edu) for details. Submission deadline for 2007 proposals is 15 March 2006.

Kansas Herpetological Society Annual Meeting

The Kansas Herpetological Society held its 32nd Annual Meeting at Pittsburg State University in Pittsburg, Kansas, on November 4–6, 2005. Over 125 participants attended scientific paper sessions presented by scientists and students from across the nation. Featured speaker was Stanley Trauth, professor at the Arkansas State University. Dr. Trauth spoke about Arkansas herpetofauna.

Lynett Bontrager, graduate student at Emporia State University, received the 2005 Howard K. Gloyd/Edward H. Taylor Scholarship, honoring the memory of two great biologists with strong ties to Kansas. The 2005 Alan H. Kamb Grant for Research on Kansas Snakes was made to George R. Pisani, Kansas Biological Survey. Larry L. Miller, Northern Hills Junior High School, Topeka, was chosen as the eighth recipient of "The Suzanne L. & Joseph T. Collins Award for Excellence in Kansas Herpetology."

In 2006, the Society will meet at the Sternberg Museum of Natural History, Fort Hays State University in Hays, Kansas.

Timber Rattlesnake Symposium

A symposium on Timber Rattlesnake (*Crotalus horridus*) Biology and Conservation in the Upper Mississippi River Valley was held on 24 September 2005, at Saint Mary's University in Winona, Minnesota. Sponsors included the Minnesota Department of Natural Resources, the Wisconsin Department of Natural Resources, and the Minnesota Herpetological Society. Nearly 100 participants from at least eleven states heard twelve presentations on timber rattlesnakes in Minnesota, Wisconsin, Iowa, and Illinois. The au-

dience included researchers, students, wardens, private landowners participating in habitat management programs, government agency personnel, and snake enthusiasts. Twenty-eight page, spiral bound program books, which include extended abstracts and seven pages of color photographs, are available for US $12.95 postpaid from Zoo Book Sales, Lanesboro, Minnesota (e-mail: zoobooks@acegroup.cc).

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

25–26 March 2006—29th Annual All Florida Herpetology Conference, Gainesville, Florida, USA. Information available at: www.flmnh.ufl.edu/herpetology/herpsconference/afhc.htm.

31 March–2 April 2006—Symposium—Conservation and Herpetology: The Middle American Connection. Miami-Dade College, Miami, Florida, USA. Information available from Larry David Wilson, organizer, by e-mail: lwilson@mdc.edu.

13–15 April 2006—53rd Annual Meeting of the Southwestern Association of Naturalists (SWAN), Universidad de Colima, Colima, Mexico. Information available at: http://www.biosurvey.ou.edu/swan/ or from Dr. Stanley Fox, SWAN President-elect (e-mail: foxstan@okstate.edu).

17–19 July 2006—49th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. New Orleans, Louisiana, USA. Information: http://www.dce.ksu/jointmeeting/.

24–27 November 2006—Herpetological Association of Africa 8th Conference. Potchefstroom campus of the North-West University, South Africa. Information available from conference organizers Louis du Preez (drklhdp@puk.ac.za) and Ché Weldon (drkcw@puk.ac.za).

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **María del Rosario Castañeda** or **Michele Johnson**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Senescence and Chemical Protection in Fishes, Reptiles, and Amphibians

Evolutionary theories of aging predict that species that experience low rates of extrinsic mortality, such as weather, predation, or disease, will have slower senescence and longer maximum life spans than their relatives with high extrinsic mortality rates. This relationship is expected because few individuals of high extrinsic mortality species will live long enough for systems that retard senescence to be selected. The authors tested this hypothesis by comparing 1193 chemically-protected (i.e., poisonous or venomous) species, which presumably are less vulnerable to mortality by predation, and their non-protected relatives in fishes, snakes, frogs, and salamanders. Data on maximum longevity, body size, and chemical defenses were collected from primary literature, zoo and laboratory records, and field guides and analyzed at both species and genus levels. Results for each phylogenetic group showed that maximum longevity was positively correlated with body size and that for a given body size, chemically-protected species have longer maximum life spans than their non-protected relatives. Somewhat surprisingly, results also suggested that smaller species are more likely to have chemical defenses than larger species. These results are consistent with evolutionary theories of senescence and support the importance of extrinsic mortality in the evolution of aging.

Blanco, M. A. and P. W. Sherman. 2005. Maximum longevities of chemically protected and non-protected fishes, reptiles, and amphibians support evolutionary hypotheses of aging. Mechanisms of Ageing and Development 126:794–803.

Convergence of Chemical Defense in Poison Frogs

Aposematically colored poison frogs are recognized in four anuran families and occur in Central and South America, Australia, and Madagascar. Poison frogs store defensive alkaloids in granular glands and generally are incapable of producing these compounds. Instead, it appears they sequester alkaloids from their arthropod prey, including beetles, ants, and millipedes. In this study, the authors conducted a survey of *Mantella* frogs from Madagascar (a genus that shares many traits with neotropical poison frogs), and their potential dietary arthropods at Ranomafana National Park. After collecting and preserving frog and arthropod specimens, gas chromatography-mass spectrometry (GC-MS) analyses detected 11 known poison frog alkaloids in the arthropod samples, 7 of which were also identified in the mantillid extracts. This study also reported the discovery of a number of alkaloids, including nicotine, previously unknown from mantillids These results suggested that the evolution of passive chemical defenses in unrelated Malagasy and Neotropical poison frogs is an example of two types of convergence: first, the convergent evolution of arthropods containing toxic alkaloids, and second, the independent evolution of alkaloid uptake and sequestration mechanisms

in these frogs.

Clark, V. C., C. J. Raxworthy, V. Rakotomalala, P. Sierwald, and B. L. Fisher. 2005. Convergent evolution of chemical defense in poison frogs and arthropod prey between Madagascar and the Neotropics. Proceedings of the National Academy of Science 102:11617–11622.

Habitat Fragmentation Causes Reduced Reproductive Investment in Lizards

The results of habitat fragmentation (e.g., reduced species richness in patches) are better known than their underlying processes, particularly as there may be species-specific responses to fragmentation. If fragmentation results in fewer resources or increased predation, females may adjust resource allocation between offspring size and offspring number. In this study, gravid female lacertid lizards (*Psammodromus algirus*) were captured in forests (≥ 200ha) and forest fragments (≤ 10ha) in northern Spain and brought into the laboratory for egg-laying. Juveniles that hatched were then released in the wild and monitored for survival. Results showed that while females from the two habitats did not differ in body condition, females from the fragments laid fewer eggs than females of similar body size from the forests, but these eggs were not larger, as would be predicted by the hypothesis of resource allocation trade-offs. Among juveniles, larger eggs produced larger offspring, and larger offspring had higher survivorship. These results showed that the reduction of reproductive output in fragmented habitats can be added to the list of negative effects of fragmentation on natural populations.

Landscape Effects on Spotted Frog Population Structure

While many models of speciation invoke landscape features such as rivers or mountains as the cause of genetic divergence, little is known regarding the effects of such features on genetic variation. Landscape features may particularly affect amphibians and other groups with poor dispersal abilities. To determine whether ridges and elevation gradients act as barriers to gene flow in Columbia spotted frogs (*Rana luteiventris*), and whether a pond represents a 'randomly mating population' (or deme), the authors examined genetic variation at six microsatellite loci in 790 adult frogs from 28 sites in western Montana and Idaho. Results showed that 1) mountain ridges generally restricted gene flow, suggesting that mountains may facilitate allopatric speciation in amphibians, and 2) there was limited gene flow between high and low elevation ponds, although dispersal may not be restricted between these elevations. The molecular data also demonstrated that, except for geographically isolated ponds, breeding populations often encompass more than one pond. The authors concluded from these results that the overall population structure of the spotted frog is a "valley-mountain" structure in which low elevation populations have large historical effective sizes and high gene flow, high elevation populations have opposite characteristics, and gene flow between high and low elevations is limited but not absent. The authors also discussed potential conservation implications of these findings.

Increase in Species Discoveries: Not a Case of Taxonomic Inflation in Amphibians

While amphibian species are declining worldwide, researchers continue to discover new species; in the last 11 years, the number of recognized amphibian species increased over 25 percent. Some attribute this increase in species numbers to taxonomic inflation, where known subspecies are raised to species status or formerly synonymous species are subdivided. The authors, however, argued that for amphibians, this increment is due to the increase in the use of bioacoustic and molecular genetic techniques, as well as an intensified effort to explore poorly studied tropical areas. Using endemic Malagasy frogs of the family Mantellidae as a representative example, the authors showed that the genetic divergence (the Kimura two-parameter distance) between recently described species and their closest previously known relatives is no greater than for species described in earlier periods. Additionally, using herpetological catalogs and museum records, they determined that most of the species described since 1992 were not the result of subdividing other species, showing that the new species are discrete evolutionary units. This finding might have significant conservation implications, as far more species might be at risk of decline or extinction than are currently recognized.

Molecular Phylogeny of Turtles

Morphological characters have long been used to resolve phylogenetic relationships among turtles, and their more recent combination with molecular data has increased statistical support of the phylogeny; however, several key nodes in this group remain

unresolved. The authors used existing mtDNA, as well as new nuDNA sequence data from the RAG-1 gene, to determine whether polytomies in the tree are an accurate representation of turtle evolution or if the additional data can clarify the relationships among the major cryptodiran groups. Using 24 species representing all major families of turtles, the authors performed maximum parsimony, maximum likelihood, and Bayesian analyses on almost the entire (~3kb) RAG-1 gene. These analyses supported most results of previous phylogenetic analyses, in some cases with higher statistical support. The RAG-1 gene also suggestd that two groups often considered sister taxa, Platysternidae and Chelydridae, are not closely related, although their precise placement on the tree remains unclear. However, the different analyses differ on the positions of the earliest branches of the turtle phylogeny. Maximum parsimony suggested three basal branches (Carettochelyidae, Trionychidae, and all other extant species), while maximum likelihood and Bayesian analyses grouped Carettochelyidae and Trionychidae as sister to all other hidden-necked turtles (Cryptodirans). The authors further discussed the utility and limitations of molecular and morphological data.

Bite Performance Best Predicts Reproductive Potential in Collared Lizards

The evolution of weapons in sexually dimorphic species is often attributed to male combat, and individual variation in these weapons is expected to play an important role in determining fitness. While laboratory experiments have shown correlations among head size, bite force, and social dominance in lizards, bite force has not yet been shown to predict fitness in natural populations. The authors studied *Crotaphytus collaris*, the collared lizard, to test the hypothesis that weapon (i.e., bite) performance was related to reproductive fitness. Collared lizard males establish territories that encompass several female territories and defend them from intruding males, with agonistic interactions between males often escalating to violent biting. The authors captured lizards to measure morphology (body size and head dimensions) and bite force and subsequently determined territory boundaries of these males. To measure potential fitness, they counted female territories overlapping with each male's territory, observed courtship encounters, and calculated potential output of the males by summing the potential reproductive output of all the overlapped females. Results showed that bite force was significantly correlated with territory size, number of female territories overlapped, estimated number of females inseminated, and potential reproductive output. Also, in several multiple regression models, bite force was the only significant predictor of fitness (i.e., morphological measures were not significant predictors). These results indicated that studies in which measures of morphology are considered to be a proxy for fitness potential should have a known underlying morphology-performance relationship.

Robotic Lizard Experiments Show Display Content is Context-Dependent

Animal displays often contain variable, and sometimes redundant, signals. These displays may evolve under sexual selection (via female choice) or from opposing selective pressures from multiple contexts (e.g., territory defense and courtship). In this study, the authors used playback experiments with a robotic lizard model to partition the complex headbob displays and body postures of the lizard *Sceloporus graciosus* into meaningful units and to determine if these units have different functions for different receivers. After determining that *S. graciosus* responded both to the robot and a live lizard with similar behaviors, they exposed lizards to combinations of natural or artificial, and single or double displays. Results showed that male lizards responded to specific body postures of the signaling robot, while female lizards responded to the number of headbob displays. These results suggested that the evolution of displays in *S. graciosus* is the result of different selective pressures in different social contexts. Interestingly, the playback experiments also showed that lizards can both respond to and imitate novel display behaviors.

Convergence and Divergence in Predator-Induced Plasticity in Newt Larvae

When multiple species are exposed to similar environments, evolutionary theory predicts that convergent phenotypes will result. Therefore, when an environment is defined by its predator composition, prey species may evolve similar anti-predator traits. The authors performed a comparative analysis of six sympatric species of newts representing both major clades of the genus *Triturus* to determine whether inducible morphological and behavioral responses to predation were convergent. Two sets of experiments were performed; in the first, larvae of each newt species were exposed to dragonfly larvae to induce phenotypic plasticity. Results showed that morphological plasticity varied among all species, while behavioral plasticity differed between the two clades but not within them. The second experiment tested whether predation risk was dependent on body size; results suggested that similar predators may affect the two differently-sized clades in different

ways. The authors offered several suggestions for why these species that occupy extremely similar environments would evolve divergent phenotypes. The species may have important unrecognized unique features, such as differences in microhabitat use. Alternatively, they may represent distinct adaptive peaks in the same environment, or they may be constrained by historical differences in habitat use.

The Mid-Domain Effect Model Applied to Green Turtle Nest Distribution

The mid-domain effect (MDE) model states that within a shared geographical domain, the greatest species richness will occur at its center after ranges of several species are randomly placed in the domain. While this model has been applied to multiple interspecific systems, the authors performed the first analysis of the MDE in an intraspecific context. In particular, they assessed the spatial and temporal nest distributions of a population of green turtles (*Chelonia mydas*) in Costa Rica that was surveyed continuously between 1972 and 2000. Results indicated that both spatial and temporal nest distributions have remained stable during this time period. Spatial nest distribution along the 18-mile beach showed a strong central tendency and closely fit predictions made using MDE model simulations. The temporal distribution, however, showed a stronger central tendency within the nesting period than the MDE model predicted. The authors discussed environmental factors that may cause observed deviations from the model.

"WHEN FIRST TAKEN CAPTIVE MOST WILD CREATURES ARE QUITE TERRIFIED AND PANICKY—THIS WAS TRUE OF THE RATTLESNAKE THAT BIT ME AND YET ON MY RETURN FROM THE HOSPITAL THIS SAME NERVOUS FELLOW WAS TAMED WITHOUT ANY TROUBLE—IT WAS DONE IN TWO WEEKS, WITH ONLY ONE HAND!"

—GRACE OLIVE WILEY IN 1930

Grace Olive Wiley (1883–1948), a librarian at the Minneapolis Public Library, wrote a letter to John J. McCutcheon, president of the Brookfield Zoo's Zoological Society on 29 January 1927, applying for the curatorial job of reptiles. In a later letter to director Edward Bean on 29 May 1933, she offered to donate her enormous private collection (115 species and 330 individuals) and a number of cages to the Zoo if the position were offered to her. During that time, it was highly unusual for women to hold curatorial positions in zoos but apparently her résumé and offer were convincing for she was hired that year (Fig. 1).

Wiley held the curatorial position for two years and her time at the Zoo was filled with controversy. She believed that venomous reptiles could be tamed and handled with bare hands, a practice that did not endear her to her superiors (Fig. 2). Although she was told to stop handling them, she refused to do so. Later in fact, Wiley wrote an article in *Natural History Magazine* in 1937, outlining her techniques for taming king cobras, Egyptian cobras,

FIG. 1. Undated picture (likely in 1933) of reptile house at Chicago Zoological Park (Brookfield Zoo) from *Minneapolis Sunday Tribune* article announcing opening and installation of Grace Olive Wiley as curator. This building still functions as an amphibian and reptile exhibit. Credit: provided by George Rabb, Chicago Zoological Society.

FIG. 2. Although there is no information attached to this photograph of Grace Olive Wiley and her friend, it appears to have been taken in the service area of the reptile building at Brookfield Zoo. Episodes such as this led to her dismissal as reptile curator in 1935.

puff adders, Australian black snakes, Australian tiger snakes, green mambas, sea snakes, coral snakes, fer-de-lance, moccasins, copperheads, thirteen species of rattlesnakes, and Gaboon vipers, which could not only be handled without any danger but enjoyed being stroked. In the article, Wiley offered this observation: "Somehow they know very, very soon that I am friendly and like them. They appear to listen intently when I stand quietly at their open door and talk to them in a low, soothing voice. In some unknown manner my idea of sympathy is conveyed to them." After a series of 19 snake escapes, some of which included three Egyptian cobras, one bandy-bandy, and several venomous sand snakes, her boss Acting Director Robert Bean lost patience and fired her in September 1935. One reason was monetary: because of her, the upcoming liability insurance payment for the Zoo was increased to the point it exceeded her annual salary.

Wiley complained to a *Time* magazine reporter on 30 September: "I hate to say it and I know some persons who don't like snakes are very nice persons but Mr. Bean was frightened and frightened persons will exaggerate. I do not feel I was guilty of carelessness. I just forgot, simply forgot, to close the door to the cobra's cage after I cleaned it. I couldn't do everything at once. All the other snakes that got away were harmless except Bandy-Bandy and I'm sure he went down the drain pipe. "The cobra,' she added, 'just found the coziest place it could in the whole reptile house. If most persons were half as nice as snakes, this world would be a better place." When a keeper put his hand into a bag of dried leaves which he planned to use for cage decorations, he found "Bandy-Bandy."

The news media followed these incidents and her career with interest. A few newspaper headlines: "Woman's Kindness Wins Deadly Snakes at Brookfield Zoo;" "19 Snakes Got Away, Grace Wiley Fired as Snakes Escape;" "Bandy-Bandy Found Alive;" "Mrs. Grace Wiley Packs Her Reptile Friends;" "Snakes Depart. Long Beach Herpetologist Taking Collection to Hollywood."

After leaving the Zoo, she had started a private roadside reptile exhibit called "Grace Wiley—Reptiles" in Cypress, California where she allowed venomous snakes, including king cobras, tiger snakes, gaboon vipers, kraits, copperheads, and rattlesnakes, to be handled by children and crawl through crowds of visitors for a small fee. Although undated with provenance unknown, the photographs in this article (Figs. 3–4) were probably taken in Long Beach, California. They were found in the collection of Wesley Dickinson, her close friend who died from a king cobra bite.

Wiley died from an Indian cobra bite. She had only one vial of anti-snakebite serum on hand because it was expensive and she needed so many types for her collection. Unfortunately, this single

FIG. 3. A delighted Grace Olive Wiley with Gila monster and rattlesnake.

FIG. 4. In this undated photo, Wiley's mother is shown with a king cobra.

glass vial of Haffkine serum was not used as it was accidentally broken shortly after the bite. She was rushed to Long Beach Hospital in an ambulance but died ninety minutes after being bitten.

Acknowledgments.—George Rabb and Ray Pawley provided materials from the Brookfield Zoo archives.

Lizard Foraging Modes: Global Need for Data, Methods for Data Collection and Call for Data

WILLIAM E. COOPER, JR.
Department of Biology, Indiana University-Purdue University at Fort Wayne
Fort Wayne, Indiana 46805, USA
e-mail: cooperw@ipfw.edu

A large majority of lizard species hunt for prey using one of two foraging modes, ambush foraging and active foraging, described informally by Evans (1961) and defined and explored theoretically by Pianka (1966) and Huey and Pianka (1981). Ambush foragers adopt posts affording unobstructed views, remain immobile while waiting for prey, and then attack prey that usually are detected visually. Active foragers search for prey by moving through the habitat and locate prey using both visual cues and chemical cues sampled by tongue-flicking (Evans 1961).

Study of foraging activity has led to important advances in our understanding of the evolution of lizard taxonomic and ecological diversity (Cooper 1997; Schwenk 1993; Vitt et al. 2003). Most species can be categorized as ambush or active foragers, but certain species do not fit the two-mode paradigm well (Butler in press; Perry 1999, in press). My goals here are to indicate lizard groups for which data are needed, present information needed to collect data, and encourage herpetologists to contribute to our collective data base on lizard foraging activity.

Data available and data needed.—The major variables in studies of lizard foraging are number of movements per minute (MPM) and percent time spent moving (PTM). PTM is a better index than MPM, but that both variables are important components of foraging activity (Cooper et al. 2001; Butler, *in press*). MPM or PTM data are available for over 150 species, but for many species data are minimal or only include one variable. If only those species for which there are data on ≥ 10 individuals for a total observation time of ≥ 100 minutes are considered, data are available for 82 species.

Data are needed for several taxonomic groups (Table 1). In Iguania, data on both variables are unavailable for any single species in Tropiduridae and Hoplocercidae and few data are available for Chamaeleonidae or for some major subtaxa in Agamidae, especially Australian groups. Data for surprisingly few phrynosomatid species are available given their diversity and wide distribution. Direct observations of horned lizards (*Phrynosoma*) are desirable because indirect observations suggest that they may forage more actively than other phrynosomatids (Shaffer and Whitford 1981). In Scleroglossa, data are lacking for anguids, gerrhosaurids, gymnophthalmids, xantusiids, xenosaurids, and varanids. Among gekkotans, we need data for several terrestrial species, especially arenicolous ones, and pygopodids. Additional data for lacertids and skinks are highly desirable due to greater variability of foraging activity than in other families. The only datum for any anguimorphan is a PTM value for *Heloderma*

suspectum (Jones 1983). Special efforts to collect data on anguids and varanids are warranted due to their importance in understanding the evolution of foraging.

Data collection.—Foraging data are simple and inexpensive to collect. Perhaps the greatest difficulty is determining motivation (Anderson 1993, *in press*). Conducting observations at inappropriate times may yield inaccurate estimates of foraging movements. Estimates based on data collected when lizards are basking or at rest digesting would lead to misleadingly low estimates of movement. Inclusion of data on movements for purposes other than foraging (territorial patrolling, courtship, aggressive behavior, and shuttling between sun and shade to thermoregulate) would inflate estimates of foraging movement. Movements unrelated to foraging should be excluded and observations should be restricted to times and conditions that favor foraging, e.g., warm and at least partially sunny weather for heliotherms. Data should not be collected during thermoregulatory basking or when lizards have stopped foraging for the day. Further discussion of data collection can be found in Anderson (1993) and Perry (*in press*).

Upon sighting a lizard, the researcher stops moving and prepares to record data. Observing from a blind would be helpful for wary species, and observing from behind trees, rocks, or other objects can be helpful with many species. If a lizard appears to be disturbed, no data should be collected. Staying still is crucial to reducing disturbance. By remaining immobile for at least two minutes or a shorter period if the lizard resumes normal activity, the researcher can maximize the likelihood of observing normal behavior. Active foragers start moving again if they have stopped, and often walk directly toward observers. Ambush foragers often make displays, postural adjustments, or head movements showing that normal behavior is occurring.

The greater the distance between researcher and lizard during observations the better for many species, but many active foragers continue normal foraging activity when followed from a distance of about 5 m. Varanids are difficult to observe because they flee upon detecting a human being at much greater distances. Some anguids and horned lizards remain motionless for extended periods after detecting an observer. Telescopes or blinds may be needed.

Data can be recorded on microcassette tapes and transcribed onto data sheets from which foraging variables can be derived. Species, date, and time are recorded, plus whether the lizard is moving or motionless. During continuous (focal) observation the researcher records all activities, using a stopwatch to indicate the time to the nearest second since the start of the focal observation when each change from moving to immobility occurs. Attacks on prey and their success or failure should be recorded, as well as whether prey were discovered through active search or ambush. Times spent on irrelevant activities such as social behavior should be recorded, but excluded. If an individual's irrelevant activities are extensive, its data should be excluded. It may be useful to record whether the lizard is in open sun, filtered sun (partially shaded), or in shade during intervals of motionlessness and movement because stops in the shade for thermoregulation are important at high temperatures. Distance moved during each movement bout should be estimated. Estimating distances requires some practice and is imprecise, but estimates should be adequate to distinguish among taxa. Brief postural adjustments of head and body or changes in body orientation involving minimal forward movement are not considered foraging movements. Lizards often pause very briefly while moving, but stops of less than one second are ignored and considered to be momentary pauses during continuous activity.

Table 1. Numbers of species for which data meeting criteria for minimal samples and observation times are available in major lizard taxa.

Taxa	MPM	PTM	Both
Iguania			
Agamidae	3	3	3
Chamaeleonidae	1	1	1
Corytophanidae	1	1	1
Crotaphytidae	2	2	2
Hoplocercidae	0	0	0
Iguanidae	2	2	2
Opluridae	1	1	1
Phrynosomatidae	9	11	9
Polychrotidae	24	16	16
Tropiduridae	1	1	0
Scleroglossa			
Gekkota			
Eublepharidae	2	2	2
Gekkonidae	13	13	13
Autarchoglossa			
Scincomorpha			
Lacertoidea			
Xantusiidae	0	0	0
Lacertidae	9	10	9
Teiidae	9	12	8
Gymnophthalmidae	0	0	0
Scincoidea			
Scincidae	9	10	9
Cordylidae	6	6	6
Gerrhosauridae	0	0	0
Anguimorpha			
Anguidae	0	0	0
Xenosauridae	0	0	0
Helodermatidae	0	1	0
Varanidae	0	0	0

Active foragers often move slowly during area-concentrated search, and may stop locomotion while poking under leaves or around stems of plants, often tongue-flicking. Because such activities reflect active search, they should be recorded as part of time spent moving (or more accurately, searching). This possible source of differences in estimates of MPM and PTM among investigators has not been discussed previously.

Most researchers have attempted to view each lizard continuously for 10–30 minutes. Perry (*in press*) found that observation intervals of less than five minutes were unreliable. When a lizard moves out of sight behind an object, it is necessary for the investigator to move (slowly and as little as possible) to a new vantage point. If the lizard is lost before the full observation period has

been completed, truncated observations can be useful. Ideally, all observations would be for the full planned interval, but if data are difficult to obtain, the criterion for duration can be shortened. At the end of the focal observation, the investigator should record shaded air temperature at 1 m and optionally substrate temperature where the lizard was sighted.

With a little practice the data are very easy to collect. From the record of number of intervals and duration of movement and total time for each focal observation, it is simple to calculate MPM and PTM. It may help to transcribe the data onto a data sheet that shows durations of movement and immobility continuously throughout the observation interval. A sample data sheet can be obtained from the author. The total number of movements divided by total minutes of observation gives MPM and total time spent moving divided by total time of observation give PTM. Time spent subduing prey and eating is excluded because the focus is on search, not consumption. Average duration per movement can be calculated from the relationship AD = 0.6PTM/MPM, which follows from the definitions PTM = 100(N x AD)/T and MPM = 60N/T, where T = total time observed in s, N = number of movements per s, and AD = average duration per movement bout in s. Average speeds during the entire interval and while moving can be calculated and later adjusted for differences in body length between species or individuals.

For the entire data set, means and standard errors of MPM, PTM, and average speeds can be calculated. If attack data were recorded, the proportion of total attacks by all individuals on prey discovered while moving (PAM) can be calculated. This variable is available for only a few species (e.g., Cooper and Whiting 1999; Cooper et al. 2001), but has great potential for indicating the relative importance of ambush and active foraging within and among species.

How many data should be collected? Perry (*in press*) found that the sample size needed for reliable estimates varies considerably among taxa, with N > 15 being adequate except for gekkonid lizards, for which sample sizes of 50 may be needed in some cases. Because data on effect of sample size exist for only three species, more information is needed. I have adopted a goal of obtaining data for at least 10 specimens and a duration of at least 100 minutes for each species and, when possible, collecting more data. However, smaller data sets can be useful because data collected by different investigators can be pooled, which is important for rare and inaccessible species.

Call for data.—Interested readers can contribute to the size and taxonomic and ecological diversity represented in our data base by collecting data on additional species, especially from the groups highlighted above as in need of study. Latin American, African, Australian, and Asian herpetologists are in exceptionally good locations to contribute data for unstudied major taxa. In addition to being added to the growing data base, new data could be the basis for natural history notes on single species or for articles on several species. I encourage individuals to contact me about needs for data from their localities and about possible collaborations.

e-mail: wlamar@uttyler.edu

The primary functions of zoological nomenclature are to provide stability and universality for zoological names to insure maximum communication of information. This is especially important

when dealing with deadly venomous organisms where accurate identification and consistent use of scientific names are fundamental to medical interventions. A recent scientific study of the rattlesnakes, genus *Crotalus*, that proposes new applications of long-established names and/or resurrection of previously unused ones (Campbell and Lamar 2004) might be thought to undermine this important process, but instead represent advances in knowledge.

Since Klauber's classic works (Klauber 1952, 1956), the species-group names of Neotropical rattlesnakes have enjoyed stability and universality of application. However, recent research indicates that several recognized taxa comprise a complex of distinct species requiring several name changes. This proposal aims to support specific names that maintain prevailing usage as much as possible, while recognizing advances in knowledge by the designation of neotypes.

Linnaeus (1758) described three species of rattlesnakes, *Crotalus horridus*, *C. dryinas*, and *C. durissus*. The type specimens of all three have been lost. Much confusion surrounded the application of these and several post-Linnean names for rattlesnakes during the 19th and early 20th centuries (see Vanzolini and Calleffo 2002, for a recent review). By the 1920s, *C. horridus* generally was used for a North American rattlesnake and *C. terrificus*, based on *Caudisona terrifica* Laurenti, 1768 (no known type specimen), was applied to a Neotropical one (e.g., Werner 1922). From 1926 onward Amaral utilized the name *Crotalus terrificus*, for the then single recognized Neotropical species, and in 1929 he placed *durissus* as a subspecies of *C. terrificus* even though *durissus* had priority.

Klauber (1941) conducted a detailed analysis of Linnaeus' brief rattlesnake descriptions, primary references (all pre-Linnean original descriptions), and secondary references (also pre-Linnean). He concluded that all three Linnean names were likely based on the Neotropical rattlesnake called *C. durissus* by Klauber and by most subsequent workers (see McDiarmid et al. 1999). However, in order to maintain stability he followed the then current usage of *C. horridus* for the North American timber rattlesnake, the type species of the genus *Crotalus*. Klauber also pointed out that *Caudisona terrifica* Laurenti, 1768, while usually treated as a new scientific name, appears to have been based on Linnaeus' description of *C. horridus* with some additions. Despite these conclusions, Klauber applied the name *Crotalus durissus durissus* to Mexico–Central American populations and *C. d. terrificus* to the South American subspecies. Unfortunately, Klauber did not take that opportunity or subsequent ones (Klauber 1952, 1956) to designate neotypes for the names in question.

Since Klauber's 1941 paper, usage has followed his arrangement, but by 1989 (Campbell and Lamar 1989), 12 additional subspecies of *C. durissus* were recognized. In the course of resurrecting or describing 10 of these, Hoge (1966) designated a neotype for *Caudisona terrifica* from "Julio de Castilho, Município Taquari" (actually Julio [sic] de Castilhos, Município Julio [sic] de Castilhos according to Vanzolini and Calleffo 2002), State of Rio Grande do Sul, Brazil. This action was not fortunate as it is extremely unlikely that any snakes forming the basis of Linnaeus' or Laurenti's descriptions of rattlesnakes came from southern Brazil (Vanzolini and Calleffo 2002).

Most recently Campbell and Lamar (2004) concluded that several populations within a polytypic *Crotalus durissus* merited separate species status. As the lost holotype of *C. durissus* was from the Claudius Grill Collection, also called the Surinam Collection, they proposed that the name properly belongs to the South American species. Klauber (1941) was aware that the type came from the Surinam Collection and concluded that the type of *C. durissus* most probably came from South America. It thus seems a reasonable inference that it came from Suriname. The restriction of the type locality by Campbell and Lamar (2004) to Paramaribo, Suriname, does not, however, of itself unequivocally establish the usage of the name *Crotalus durissus durissus* for a Suriname population. These authors did clarify the nomenclatural complexities as first revisers (Art. 24, International Code of Zoological Nomenclature 1999) by explicitly selecting *Crotalus durissus* Linnaeus, 1758 over *C. dryinas* Linnaeus, 1758 because of the universal prevailing usage of *C. durissus*.

Campbell and Lamar (2004) also recognized as distinct species two taxa considered as subspecies of *C. durissus* by all workers subsequent to Klauber (1952, 1956). The first is *Crotalus totonacus* Gloyd and Kaufield, 1940, from northeastern Mexico. The second includes Klauber's (1952, 1956) *C. d. durissus*, *C. d. culminatus* Klauber, 1952, and *C. d. tzabcan* Klauber, 1952. Because the name *C. durissus* was applied by Campbell and Lamar (2004) to the South American rattlesnake they exhumed the name *Crotalus simus* Latreille, 1801, a name not used as valid for over 150 years, for the other Mexico–Central American populations. The name *C. simus* is based on the very same specimen, formerly in the Museum d'Histoire Naturelle (Paris), that was the model (Daudin 1803:321) for the illustration in Seba (1735, pl. 45, fig. 2) as referred to by Latreille in the original description. Klauber (1941) earlier had pointed out that Seba's plate clearly is of the Mesoamerican species. Unfortunately, the holotype of *C. simus* could have come from any one of the four recognized taxa of rattlesnakes from Mexico–Central America so correct application of the name is in doubt.

In order to clarify the situation and establish names for the involved species of Neotropical rattlesnakes we take the following actions:

1. Designate Nationaal Naturhistorisch Museum, Leiden (RMNH) 12857, an adult male, from near 2.5 km east of Tibiti, Saramacca District, Suriname (ca. 5°33'N, 55°54'W), as the neotype of *Crotalus durissus* Linnaeus, 1758, as defined and diagnosed in Campbell and Lamar (2004:539–547). The original type specimen has long been lost (Klauber 1952) but was probably South American in origin and most likely came from Suriname.

2. Designate University of Texas, Arlington (UTA-R 52032), an adult male from vicinity of El Arenal, San Vicente, Departamento de Zacapa, Guatemala, 360 m elevation (14.880176°N, 89.861817°W) as the neotype of *Crotalus simus* Latreille, 1801 as defined and diagnosed in Campbell and Lamar (2004:583–586). A search by Thireau (1991:4) of the collections in the Museum National d'Histoire Naturelle, Paris failed to locate the holotype, which was labeled as being from "Ceylon" and it is presumed lost. However, the specimen must have come from Mesoamerica based on the distinctive neck pattern of paravertebral dark stripes in combination with the dorsal color pattern of mostly non-overlapping, light-centered diamonds that are characteristic of *C. simus*. There are, of course, no known rattlesnakes from Asia.

With these actions we insure that the name *Crotalus durissus* will continue to be used for the majority of populations referred to by that name since 1941 and that *Crotalus simus* will be associated unambiguously with a Mexico-Central American species of Neotropical rattlesnake.

Body Temperatures of Free-Ranging Softshell Turtles (*Apalone spinifera*) in a Small Stream

MICHAEL V. PLUMMER[1]
TRISHA L. CRABILL[2]
NATHAN E. MILLS
and
STEVE L. ALLEN
Department of Biology, Box 12251, Harding University Searcy, Arkansas 72149, USA

[1]*Corresponding author; e-mail: plummer@harding.edu*

[2]*Present address: Department of Biological Sciences Towson State University, Towson, Maryland 21252, USA*

The thermal ecology of freshwater turtles is based largely on studies of a relatively few species in which, typically, body temperatures are highly variable, average approximately 24–28°C, and commonly track water temperatures. Basking is a common, but not universal (e.g., *Chelydra*, Brown et al. 1990; *Pseudemydura*, King et al. 1998) behavior associated with elevating body temperature. However, even for the many species that do in fact bask, whether heat gained from basking uncouples body temperatures from water temperatures long enough to be biologically significant in thermoregulation has long been debated and likely varies with species and locality (e.g., Auth 1975; Boyer 1965; Crawford et al. 1983; Di Tranni and Zuffi 1997; Manning and Grigg 1997; Moll and Legler 1971; Schwarzkopf and Brooks 1985; Spotila et al. 1990).

Compared to the various semi-aquatic turtles for which thermal biology has been studied (mostly emydids), it would seem that certain features of the highly aquatic trionychid turtles might impact their thermal ecology. For example, highly aquatic turtles, such as trionychids, (1) have a lower critical thermal maximum (CTM) than semi-aquatic species, such as emydids (Hutchison et al. 1966, 1979); (2) the flat shell of softshells enhances the rate of radiant heat exchange (Boyer 1965); (3) the cutaneous surface area of softshells is the highest known among turtle species (Stone and Iverson 1999); and (4) softshells have the highest rate of evaporative water loss of any known reptile, 3–4 times that of the emydid *Trachemys* (Robertson and Smith 1982). High evaporative water loss causes trionychids, unlike emydids, to cool faster than they heat in air (Smith et al. 1981) and can depress surface and core body temperatures, at least in the laboratory (Khosatzky 1981; Robertson and Smith 1982).

Although the physiology related to various thermal characteristics of trionychid turtles has been studied in the laboratory (Boyer 1965; Hutchison et al. 1966, 1979; Khosatzky 1981; Nebeker and Bury 2001; Robertson and Smith 1982; Smith et al. 1981), field thermal data are extremely sparse. The only available thermal data for free-living trionychid turtles include a few ambient water temperatures measured opportunistically for *A. mutica* and *A. spinifera* (Graham and Graham 1991; Plummer 1977; Williams and Christiansen 1981) and body and ambient water temperatures of hibernating *A. spinifera* measured with temperature-sensitive radiotransmitters (Plummer and Burnley 1997). Body tempera-

tures have not been reported for any free-living trionychid species during their active season. The purpose of this paper is to provide basic field information on softshell thermal ecology by describing body temperatures of free-living *A. spinifera* in a small stream.

Materials and Methods

We have studied a population of *Apalone spinifera* by mark-recapture in Gin Creek, a first-order tributary (average width = 4–5 m, depth = ~35 cm) of the Little Red River in White County, Arkansas since 1994 (unpubl. data). A detailed description of the study area is given by Plummer et al. (1997). Softshells were captured by hand or in funnel traps. Of the approximate 300 marked turtles (50 adults) in the population, only adult females were used in the present study because, compared to males, their larger body size facilitated implantation of transmitters and data loggers. Similar body sizes of the selected females (200–240 mm plastron lengths) reduced possible size-related differences in heating and cooling rates. For each softshell, plastron length (PL) and body weight were measured, a unique mark was provided, and a transmitter (Model SM-1, AVM Instrument Co., Livermore, California) was attached to the posterior part of the carapace prior to its release at its site of capture. Beyond these common methods, data were collected differently in 1995 and 2000.

In addition to the attached transmitter, in 1995 a second temperature-sensitive transmitter (Model CHP-2P, Telonics, Inc., Mesa, Arizona) was surgically implanted in each of four adult females. Implanted transmitters (6 x 12 x 30 mm, 6–7 g) were inserted into the body cavity through a small incision made in the body wall anterior to the hind legs near the bridge. The incision was closed with nylon sutures. Combined mass of the attached and implanted transmitters was <1% of turtle mass.

In 1995, each softshell was located each day during their activity season (15 Mar–29 Oct). At each location, the pulse rate of the temperature-sensitive transmitter, water temperature, and air temperature were recorded. We also attempted to determine the turtle's behavior (active, inactive, buried, basking). Transmitter pulse rates were later converted to temperatures from calibration curves constructed previously for each transmitter. At the end of the study period, turtles were recaptured and taken to the lab where implanted transmitters were removed and the incision closed. Turtles were then released at the site of their last capture.

In 2000, a TidBit® temperature data logger (Onset Computer Corp., Pocasset, Massachusetts) was surgically implanted in the body cavities of two adult females using the surgical procedures outlined above. The combined mass of TidBits (17 x 21 mm, 21 g) and attached transmitters was <3% of turtle mass. TidBits were programmed to record temperatures at 5 min. intervals. After implantation, turtles were released into the field. From 11 May to 17 August 2000, we infrequently and irregularly located turtles and attempted to determine their behavior (active, inactive, buried, basking). At the end of the study period, turtles were recaptured and taken to the lab where implanted data loggers were removed for downloading and the incision was closed. Turtles were then released into the field at the site of their last capture.

Basking events were indirectly identified in 2000 by comparing body temperature traces with concurrent water temperatures. Sharp increases (at least 4°C within 60 min.) in sequential body temperatures relative to water temperatures were assumed to represent aerial basking events (Fig. 1). This technique was highly conservative as basking events not resulting in sharp increases in body temperatures could not be identified. For example, brief basking events and basking events occurring in the shade, late in the season when water temperatures were warm, or early in the morning on overcast days may not have been detected on the temperature traces.

To obtain concurrent minimum environmental temperatures available to softshells in 2000, a TidBit data logger was suspended in a pool at a shaded 25 cm depth about 30 m upstream of a low water dam. The pool maintained an approximate constant water level during the course of data collection. To obtain concurrent maximum environmental temperatures available to aerially basking softshells, we constructed a metal softshell model painted medium flat gray and containing a TidBit data logger. At nonlethal temperatures (<35°C) produced in the laboratory with radiant heat, equilibrium temperatures of a tethered softshell and the model were similar. In the field, the model was placed near a known softshell basking site on the stream bank that was exposed to full sunlight throughout the day.

Statistical analyses were conducted with SYSTAT (SYSTAT, 2002). For data that were normally distributed and had homogeneous variances, paired-samples t-tests with Bonferroni probabilities were used to compare body temperatures between buried/basking and early/late season for individual turtles. A nonparametric Wilcoxon test was used to compare body temperatures between active/inactive individual turtles because the data did not meet parametric assumptions. Coefficients of determination (r^2) were used to describe the relative amount of variation in body temperature that was explained by water and air temperatures. Unless otherwise stated, means are accompanied by one standard error.

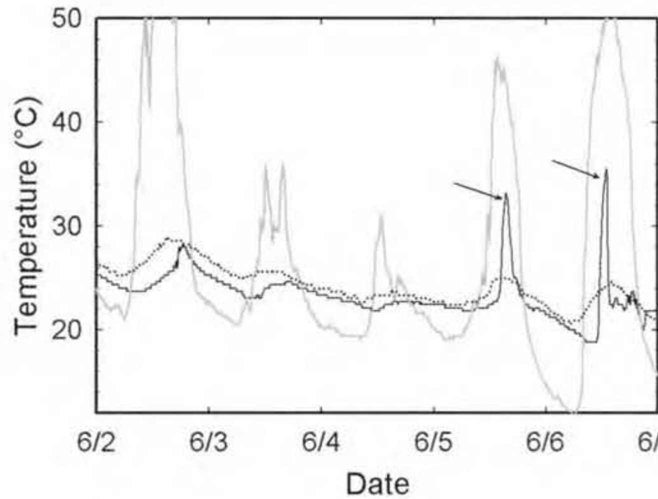

FIG. 1. Water temperatures (dotted line), model temperatures (gray line), and body temperatures (solid line) of an *Apalone spinifera* on representative days in 2000. Model temperatures were relatively high on 2, 5, and 6 June, but basking occurred only on 5 and 6 June. Arrows indicate spikes in body temperature that were assumed to result from aerial basking on 5 and 6 June. On 3 and 4 June, model temperatures were relatively low; apparently no basking occurred as body temperatures tracked water temperatures with little variance throughout the day.

TABLE 1. Times monitored and body temperatures (°C) of active (moving), inactive (nonmoving), buried in stream substrate, and aerially basking *Apalone spinifera* in 1995. Shown are mean, standard error, and sample size (in parentheses).

	Turtle Number			
Category	4	16	63	80
time	15 Mar–27 Sep	15 Mar–24 Oct	21 Jul–24 Oct	21 Jun–24 Oct
active	25.5 ± 0.42 (76)	25.5 ± 0.42 (95)	27.0 ± 0.65 (39)	27.6 ± 0.6 (39)
inactive	24.0 ± 0.60 (95)	23.0 ± 0.65 (85)	24.3 ± 0.66 (51)	25.7 ± 0.56 (60)
buried	19.9 ± 1.26 (3)	29.3 ± 1.25 (11)	28.5 (1)	28.4 ± 0.98 (15)
basking	25.4 ± 1.78 (9)	28.9 ± 0.82 (12)	(0)	26.3 ± 1.59 (4)

RESULTS

For 1995, a total of 677 body temperatures were measured on four *A. spinifera* throughout their activity season. Categories of body temperatures that could be associated with concurrent turtle behavior were generally similar among the four turtles (Table 1). Body temperatures, pooled from all four turtles, averaged 25.2 ± 0.20°C (range 12.8–34.0°C). Pooled body temperatures of active turtles averaged 26.1 ± 0.25°C (15.2–33.2°C, N = 249) and those of inactive turtles averaged 24.1 ± 0.32°C (21.8–33.4°C, N = 291). Variation in water temperature explained more variation in body temperature among the four turtles (73–89%; mean 81%) than did air temperature (60–63%; mean 62%). Water temperature explained more variation in body temperatures of inactive turtles (78–97%; mean 89%) than active turtles (62–87%; mean 74%). Body temperatures were statistically higher when turtles were active than when inactive for three of the four turtles (Table 1; Wilcoxon, no. 4, Z = -6.05, P < 0.001; no. 16, Z = -5.14, P < 0.001; no. 63, Z = -2.21, P < 0.05; no. 80, Z = 1.02, P > 0.30). For inactive turtles, body temperatures when buried (27.9 ± 0.82°C, 18.0–34.0°C, N = 30) did not differ from basking turtles (27.2 ± 0.84°C, 17.0– 32.9°C, N = 25; Table 1; no. 4, t = -6.50, P > 0.30; no. 16, t = 0.65, P > 0.60; no. 80, t = 1.03, P > 0.50). This lack of significance could have resulted from the small sample size or because softshells often buried in very warm water. On several occasions in 1995, we captured softshells buried in substrates that exceeded 33°C.

For 2000, a total of 40,287 body temperature measurements were recorded. Overall body temperature averaged 25.0 ± 0.05°C (17.9 –37.9°C) and the distributions of body temperatures were similar between turtles (Fig. 2A). Water temperature explained 65–67% of the variation in body temperature in two turtles. At night (2200–0600 h), water temperature explained 78–84% of the variation in body temperatures compared to 60–63% in the day (0600–2200 h). Body temperatures in late season averaged 2–4°C higher than in early season (t = 115.31, P < 0.001; Table 2; Fig. 2B). Higher seasonal body temperatures were associated with an average 3.5°C higher water temperature and 4.5°C higher model temperature in July and August in 2000.

Opportunities for aerial basking to raise body temperature were rarely constrained by low environmental temperatures as maxi-

TABLE 2. Body temperatures (°C) of two *Apalone spinifera* in 2000. Shown are mean, standard error, and minimum-maximum (in parentheses).

Turtle No.	Entire Season (May–August)	Early Season (May–June)	Late Season (July–August)
15	25.7 ± 0.02	24.2 ± 0.02	27.6 ± 0.02
	(17.9–37.9)	(17.9–35.5)	(21.9–37.9)
189	25.1 ± 0.02	24.5 ± 0.02	28.5 ± 0.04
	(18.8–35.9)	(18.8–35.9)	(25.0–32.8)

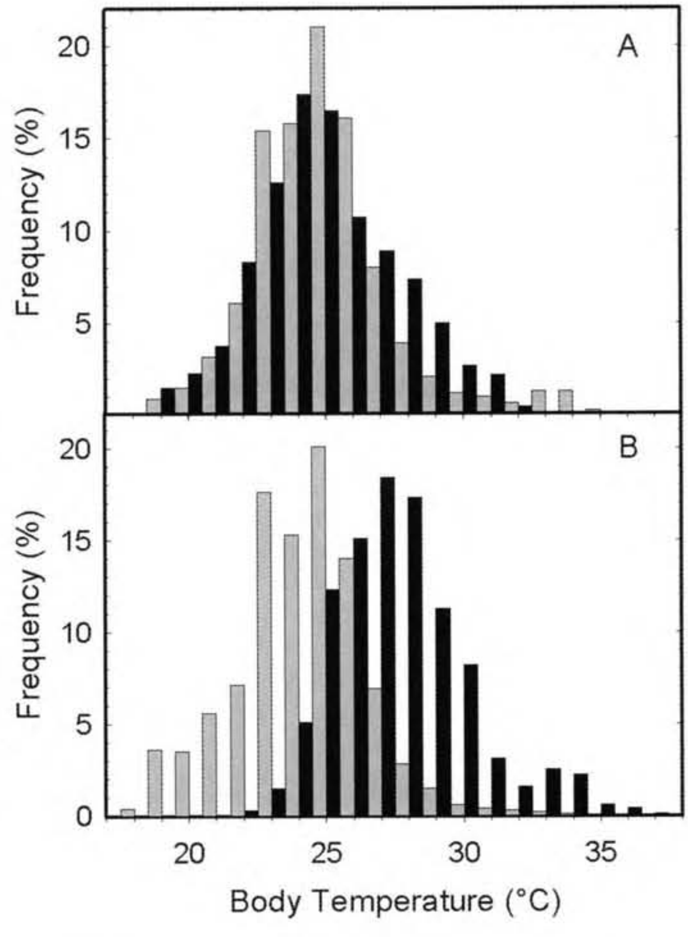

FIG. 2. A. Histogram of body temperatures for two *Apalone spinifera* during the same time period in 2000 (20 May – 6 July; N = 13,680 each turtle). During this period, mean body temperature for turtle no. 15 (dark bars) was 25.1 ± 0.023°C and that for no. 189 (gray bars) was 25.0 ± 0.023°C. B. Histogram of body temperatures for *Apalone spinifera* no. 15 in early season (May–June; gray bars) and late season (July–August; dark bars) in 2000. Mean early season body temperature was 24.2 ± 0.02°C (N = 14,678) and that for late season was 27.6 ± 0.02°C (N = 11,631).

TABLE 3. Statistics of basking in two *Apalone spinifera* as determined from a comparison of body temperature and water temperature tracings in 2000. Shown are turtle number, number of days monitored, number and percent of days that included a basking event, total number of basking events, average number of basking events per day, average number of basking events per day for days that included a basking event, and length in minutes of basking events (mean, SD, min.–max.).

Turtle No.	No. Days	No. Basking Days (%)	No. Basking Events	No. Events/ Day	No. Events/ Basking Day	Length of Basking Event (min)
189	49	25 (51.0)	42	0.86	1.7	104 ± 95 (10–415)
15	96	45 (46.8)	80	0.83	1.8	122 ± 91 (16–560)

mum model temperature exceeded 35°C on 90 of 94 days during the study period. Results from our highly conservative method of identifying aerial basking suggested that each turtle basked about 1.5–2 times per day on at least half of the days it was monitored (Table 3). Basking events averaged 1.5–2 h in length and were highly variable (CVs ~75–90%). We visually observed a total of seven aerial basking events in the field, six of which were later independently identified from the downloaded body temperature data.

Discussion

The few temperature data available for softshells include preferred ambient temperatures for *T. sinensis* in the laboratory (20–25°C; Khosatzky 1981), ambient water temperatures for free-living *A. mutica* early and late in the activity season (13.5–25.5°C; Plummer 1977), preferences of juvenile *A. mutica* in a laboratory thermal gradient (~27°C; Nebeker and Bury 2001), body temperatures of basking *A. ferox* in the laboratory (26.5–35.2°C, mean = 32.7°C; Boyer 1965), and for *A. spinifera*, ambient water temperatures of buried turtles (Graham and Graham 1991) and a telemetered free-living individual (~30°C; Williams and Christiansen 1981), and the preferred (32.7°C), voluntary maximum (35.7°C), and CTM (41°C) determined from individuals in the laboratory (Hutchison et al. 1966). Our estimates of average field body temperatures for *A. spinifera* are toward the low end of the range of body temperatures reported for trionychids in the literature, and were remarkably similar using different methods in two different years (25.2°C in 1995 and 25.0°C in 2000). Highly aquatic turtles, such as softshells, often have lower CTMs than semi-aquatic or terrestrial turtles (Hutchison et al. 1966) and a lower CTM often indicates lower optimum body temperatures during activity for some reptiles (Huey 1982). Nebeker and Bury (2001) found a lower thermal preference for hatchlings of the highly aquatic *A. mutica* compared to the semi-aquatic emydid *Pseudemys nelsoni*.

Softshells appear to function as thermoconformers much of the time, with body temperature tracking water temperature. The higher r^2 values for body and water temperatures for nighttime periods and for inactive turtles reflect basic softshell natural history, i.e., diurnal turtles that spend large amounts of time burrowed in the substrate under water (Ernst et al. 1994). The difference also suggests that daytime-active softshells thermoregulate to some degree. Comparison of early-season and late-season data from both 1995 (Table 1) and 2000 (Table 2; Fig. 2) further emphasizes the large effect that water temperature has on body temperature. Periods of elevated body temperatures resulting from aerial basking occur commonly, but generally are of brief duration and do not result in a "plateau" of regulated body temperature over an extended period as often occurs in terrestrial reptiles and in some semi-aquatic turtles that shuttle between land and water (e.g., *Emydoidea*, Sajwaj and Lang 2000). Our observations suggest that, despite fundamental differences in behavior (highly aquatic), body shape (flattened), and physiology (high cutaneous surface area and evaporative water loss), field body temperatures of trionychids are similar to that of other freshwater turtles in levels of preference and variation and that softshells appear to most often function as thermoconformers as do many other freshwater turtle species.

The assumption that body temperature spikes indicated aerial basking events was supported by the fact that six of seven basking events directly observed in the field were independently identified on the temperature traces. Aerial basking is a common occurrence for *A. spinifera* in Gin Creek (~50% of days; ~2/d/turtle) and can result in elevated body temperatures. These results compare favorably with Auth's (1975) direct observations of basking in *Pseudemys scripta* (44% of days; 2–3/d/turtle, up to 5/d in favorable weather) especially given that our highly conservative indirect method likely failed to detect every basking event. In addition to aerial basking, we observed *A. spinifera* practicing partial aerial basking (i.e., body partially submerged; N = 5 observations), as did Graham and Graham (1997) and Plummer and Burnley (1997).

Basking may have several functions in turtles (summarized in Boyer 1965; Moll and Legler 1971). For some species, thermoregulatory heat gain is primary (e.g., Crawford et al. 1983; Spotila et al. 1990) whereas other turtles commonly bask without raising body temperature (e.g., Manning and Grigg 1997). Aerial basking coupled with terrestrial behavior may be important in the daily and seasonal thermal strategy of semi-aquatic turtles such as *Emydoidea* (Sajwaj and Lang 2000) and *Clemmys* (Litzgus and Brooks 2000), but *Apalone* species are highly aquatic and typically leave water only briefly to nest and bask (Ernst et al. 1994; MVP pers. obs. 1975, 2003). We do not deny the importance of basking in *Apalone* spp. as it apparently is a widespread, commonly occurring behavior the specifics of which differ among sympatric *Apalone* species (Lindeman 2001) and possibly between the sexes (Plummer 1977). Nevertheless, considering the behavior of softshells and a morphology/physiology that promotes rapid environmental heat exchange, we doubt whether body temperatures of basking *Apalone* are uncoupled from water temperatures long enough to be of thermoregulatory significance in their over-

all thermal strategy (Congdon 1989).

Acknowledgments.—We thank S. Allen, C. Burnley, J. Demuth, and G. Smith for assistance in the field, J. Moon for providing logistical support, and H. and I. Lisle for providing a pleasant environment for writing. Turtles were collected under Scientific Collecting Permit No. 675 issued by the Arkansas Game and Fish Commission. This research was approved by the Harding University Animal Care Committee and followed the guidelines in the booklet, "Guidelines for Use of Live Amphibians and Reptiles in Field Research" (1987; American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles). This research was supported in part by several Faculty Development grants from Harding University.

At present, 160 species of amphibians (composed exclusively of Anura and Gymnophiona) are known from Borneo (Das 2005; Das and Haas 2005; Inger and Stuebing 2005). The last summary of knowledge on their larval forms, compiled by Inger (1985), revealed that 45–60% of the fauna then described (63 larval forms), had known larval stages. An additional 14 larval forms could not be assigned to the parent species at the time. Some progress has been made in the two decades that has now elapsed, through the

discovery and allocation of additional tadpoles to their parent species within Borneo and extralimitally.

This review provides an annotated list of Bornean species of amphibians, along with details of larval forms in the literature, and was prepared as a precursor to a project, supported by a grant from Volkswagen Stiftung, to match amphibian larvae to their parent species from Borneo, using DNA sequence data.

The quality of description of Bornean amphibian larvae as found existing in the literature varies significantly, as noted by Inger (1985), and is also true for other faunas (see for instance, Leong [2002], for a similar account of the status of the tadpoles of the Malay Peninsula). In this treatment, we scored larval descriptions from 0–7, where 0 = unknown; 1 = abbreviated description; no figure; 2 = abbreviated description; with figure; 3 = extended description; no figure; 4 = extended description; with figure; 5 = scanning electronic micrography (SEM); 6 = no description, non-SEM image; and 7 = measurements; no description or images. Additionally, X = those with direct development (*Philautus* spp.).

The respective references cited are in chronological order. Mention is made if descriptions are based on extralimital samples, and indicated with 'B', if drawn from Borneo. Where not specified, these are from unspecified localities.

In total, 89 species of amphibians known from Borneo now have known tadpoles. This represents 55.6% of the known Bornean amphibian fauna. Additionally, the larvae of several species (including *Bufo quadriporcatus*, *Kaloula baleata*, *K. pulchra*, *Microhyla berdmorei*, *Fejervarya cancrivora*, *Rana erythraea*, *Rhacophorus cyanopunctatus*, *R. reinwardtii*, and *Theloderma horridum*) have been described exclusively from extralimital areas (including China, India, Sri Lanka, Thailand, the Malay Peninsula, Java and the Philippines Archipelago). Given the systematic uncertainties with several lineages, it is unclear at least in some cases (e.g., *Kaloula baleata* and *Fejervarya cancrivora*) whether the allocation would be relevant to Bornean populations of the respective species.

Groups with unknown larval stages include the sole Bornean representative of the Bombinatoridae (comprising *Barbourula kalimantanensis*, a poorly-known endemic of Kalimantan, Indonesia); 13 species of Bufonidae; 13 species of Microhylidae; 10 species of Megophryidae; 13 species of Ranidae; 20 species of Rhacophoridae; and five species of Ichthyophiidae. Ecological correlates are also evident. For instance, a large number of species from relatively inaccessible peat swamp habitats have unknown larval forms (including *Pseudobufo subasper*, *Limnonectes kenepaiensis*, *L. paramacrodon*, *Rana baramica*, and *R. laterimaculata*). Six of eight endotrophic tadpoles of the bufonid genus *Pelophryne* too remain unknown, in addition to all but one *Philautus*, a rhacophorid genus with 17 Bornean species, containing species showing direct development.

When larval descriptions are available, these may be in an abbreviated form, or no vouchers are listed, making identities uncertain. Examples include descriptions of larval *Leptobrachium montanum* and of *Rana signata*: both these names are now known to contain more than a single species (see Brown and Guttman 2002; Malkmus et al. 2002). In other cases, larval descriptions are so general that species identification below generic level is hardly possible.

Acknowledgments.—We thank our respective institutions, the Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak and Biozentrum Grindel und Zoologisches Museum, Universität Hamburg, for supporting our researches. We are grateful to Volkswagen-Stiftung, Germany (grant I/79 405) for supporting our research on larval systematics and ecology, and A. Haas acknowledges the Economic Planning Unit, at the Prime Minister's Office, Kuala Lumpur, for issuing a research permit. We thank Kelvin K. P. Lim and Van Wallach for literature, Patrick David for help with the dating of the Bourret (1942a) paper, and W. Ronald Heyer, Robert F. Inger, and Tzi-Ming Leong, for comments.

TABLE 1. Checklist of amphibians of Borneo, annotated with status information on larval descriptions and their sources. Status of descriptions: 0 = unknown; 1 = abbreviated description; no figure; 2 = abbreviated description; with figure; 3 = extended description; no figure; 4 = extended description; with figure; 5 = scanning electronic micrography (SEM); 6 = no description, non-SEM image; 7 = measurements; no description or images; and X = direct development.

	Status of description
Bombinatoridae	
Barbourula kalimantanensis	0
Bufonidae	
Ansonia albomaculata	3 (Inger, 1985: B)
Ansonia anotis	1 (Inger et al., 2001: B)
Ansonia fuliginea	0
Ansonia guibei	2 (Malkmus et al., 2002: B); 4, 5 (Malkmus and Kosuch, 2000: B)
Ansonia hanitschi	1 (Malkmus et al., 2002: B)
Ansonia latidisca	0
Ansonia leptopus	4 (Inger, 1992a: B)
Ansonia longidigita	1 (Malkmus et al., 2002: B), 2 (Manthey and Grossmann, 1997: B), 4, 5 (Inger, 1985: B)
Ansonia minuta	1 (Inger, 1966: B); 3 (Inger, 1985: B)
Ansonia platysoma	0
Ansonia spinulifer	2 (Malkmus et al., 2002: B)
Ansonia torrentis	0
Bufo asper	1 (Bourret, 1942a: Indo-China; Manthey and Grossmann, 1997; Smith, 1930); 2 (Iskandar, 1998: Java and Bali, Indonesia; van Kampen, 1910; Nieden, 1923; Bourret, 1942b); 3 (Inger, 1985: B); 4 (Berry, 1972: Peninsular Malaysia)
Bufo divergens	1 (Inger, 1966: B; Malkmus et al., 2002: B)
Bufo juxtasper	1 (Manthey and Grossmann, 1997); 2 (Malkmus et al., 2002); 4, 5 (Inger, 1985: B)
Bufo melanostictus	1 (Boulenger, 1912; Bourret, 1942a: Indo-China; Inger, 1966); 2 (Pope, 1931: Hainan, China; Bourret, 1942b: Indo-China; Kirtisinghe, 1957: Sri Lanka; Manthey and Grossmann, 1997); 3 (Leong and Chou, 1999: Singapore); 4 (Chou and Lin, 1997: Taiwan, Republic of China); 6 (Iskandar, 1998: Java and Bali, Indonesia; Fei and Ye, 2001: China; Yang, 1998: Taiwan, Republic of China; Nutaphand, 2001: Thailand).
Bufo quadriporcatus	4 (Leong and Chou, 1999: Singapore)
Leptophryne borbonica	1 (Iskandar, 1998: Java and Bali, Indonesia); 2 (Berry, 1972; Malkmus et al., 2002; Manthey and Grossmann, 1997); 3 (Inger, 1985: B); 4 (Berry, 1972: Peninsular Malaysia)
Pedostibes everetti	0
Pedostibes hosii	2 (Manthey and Grossmann, 1997: B); 4 (Inger, 1966: B); 4, 5 (Inger, 1985: B)
Pedostibes maculatus	0
Pedostibes rugosus	0
Pelophryne api	0
Pelophryne brevipes	4 (Alcala and Brown, 1982: Mindanao, Philippines)
Pelophryne exigua	0
Pelophryne guentheri	0
Pelophryne macrotis	0
Pelophryne misera	2 (Malkmus et al., 2002: B); 6 (Malkmus, 2002: B)
Pelophryne rhopophilus	0
Pelophryne signata	2 (Manthey and Grossmann, 1997: B, as *Pelophryne brevipes;* description a composite of *P. brevipes* and *P. signata*); 3 (Inger, 1985: B, as *Pelophryne brevipes*)
Pseudobufo subasper	0
Microhylidae	
Calluella brooksi	0
Calluella flava	0
Calluella smithi	0
Chaperina fusca	1 (Parker, 1934; Bourret, 1942b; Inger, 1956: B, developmental notes; Inger, 1966: B);); 2 (Manthey and Grossmann, 1997; Malkmus et al., 2002); 4, 5 (Inger, 1985: B)
Gastrophrynoides borneensis	0
Kalophrynus baluensis	0
Kalophrynus eok	0
Kalophrynus heterochirus	0
Kalophynus intermedius	0
Kalophrynus nubicola	0

TABLE 1. Continued.

	Status of description
Kalophrynus pleurostigma	1 (Parker, 1934; Bourret, 1942b; Inger, 1956: developmental notes; Inger, 1966: B; Malkmus et al., 2002: B); 2 (Lim and Ng, 1991: Singapore; Manthey and Grossmann, 1997; Leong and Chou, 1999: Singapore); 3 (Inger, 1985: B); 4 (Berry, 1972: Peninsular Malaysia); 6 (Lim and Lim, 1992: Singapore; Iskandar, 1998: Java and Bali, Indonesia)
Kalophrynus punctatus	0
Kalophrynus subterrestris	0
Kaloula baleata	1 (van Kampen, 1910: Java, Indonesia); 6 (Iskandar, 1998: Java and Bali, Indonesia)
Kaloula pulchra	1 (Smith, 1930; Parker, 1934: Thailand; Inger, 1966: Thailand); 2 (Smith, 1916: Thailand; Annandale, 1917: Singapore; Bourret, 1942b: Thailand; Manthey and Grossmann, 1997; Leong and Chou, 1999: Singapore; Malkmus et al., 2002); 6 (Nutaphand, 2001: Thailand; Chan-Ard, 2003: Thailand)
Metaphrynella sundana	0
Microhyla berdmorei	1 (Parker, 1934: Annam, Vietnam; Inger, 1966: Annam, Vietnam); 2 (Smith, 1924: Indo-China; Bourret, 1942b); 4 (Leong, 2004: Peninsular Malaysia)
Microhyla borneensis	1 (Parker, 1934; Inger, 1966: B; Malkmus et al., 2002); 2 (Leong and Chou, 1999: Singapore); 4, 5 (Inger, 1985: B)
Microhyla maculifera	0
Microhyla perparva	3 (Inger, 1985: B); 4 (Inger and Frogner, 1979: B)
Microhyla petrigena	1 (Malkmus et al., 2002: B); 4 (Inger and Frogner, 1979: B); 4, 5 (Inger, 1985: B)
Megophryidae	
Leptobrachella baluensis	0
Leptobrachella brevicrus	0
Leptobrachella mjobergi	3 (Inger, 1985: B); 4 (Dring, 1983b: B); 4, 5 (Inger, 1983: B)
Leptobrachella parva	0
Leptobrachella palmata	0
Leptobrachella serasanae	0
Leptobrachium abbotti	2 (Malkmus et al., 2002: B); 4, 5 (Inger, 1985: B, a composite of *Leptobrachium abbotti* and *L. montanum*)
Leptobrachium gunungense	2 (Malkmus et al., 2002: B)
Leptobrachium hendricksoni	1 (Inger, 1983: B; 1985: B); 2 (Manthey and Grossmann, 1997)
Leptobrachium montanum	2 (Manthey and Grossmann, 1997: B; Malkmus et al., 2002: B); 3 (Inger, 1983: B: probably a composite of *Leptobrachium montanum* and *L. abbotti*); 4, 5 (Inger, 1983: B, probably a composite of *L. montanum, L. abbotti,* and possibly also *L. gunungense;* Inger, 1985: B, a composite of *Leptobrachium abbotti* and *L. montanum*); 6 (Malkmus, 1999)
Leptobrachium nigrops	1 (Inger, 1966: B, allocation to parent species tentative); 2 (Matsui, 1979: B, questionably assigned to *Leptobrachium nigrops;* Manthey and Grossmann, 1997; Leong and Chou, 1999: Singapore); 3 (Inger, 1985: B); 4 (Berry, 1972: Peninsular Malaysia); 4, 5 (Inger, 1983: B)
Leptolalax arayai	2 (Malkmus et al., 2002: B); 6 (Malkmus, 1999)
Leptolalax dringi	0
Leptolalax gracilis	2 (Matsui, 1979: B); 3 (Inger, 1985: B); 4, 5 (Inger, 1983: B). Grandison's (1982) description of larvae from Peninsular Malaysia is incertae sedis, as this species is not known from Peninsular Malaysia)
Leptolalax hamidi	0
Leptolalax maurus	0
Leptolalax pictus	0
Megophrys baluensis	2 (Matsui, 1979: B; Malkmus et al., 2002: B)
Megophrys edwardinae	0
Megophrus kobayashii	2 (Malkmus et al., 2002: B); 6 (Malkmus, 1999)
Megophrys nasuta	1 (Inger, 1966: B); 2 (Manthey and Grossmann, 1997; Leong and Chou, 1999: Singapore; Malkmus et al., 2002: B); 4, 5 (Inger, 1985: B)
Ranidae	
Fejervarya cancrivora	1 (Schijfsma, 1932: Java, Indonesia; Bourret, 1942a: Indo-China; Alcala, 1962: Philippines; Inger, 1966: B); 2 (Bourret, 1942b); 4 (Alcala, 1962: Negros, Philippines; Leong and Chou, 1999: Singapore)
Fejervarya limnocharis	1 (van Kampen, 1910: Java, Indonesia; Smith, 1916: Thailand; Schijfsma, 1932: Java, Indonesia; Bourret, 1942a: Indo-China; Inger, 1966; Malkmus et al., 2002); 2 (Annandale, 1917: India; Pope, 1931: Hainan, China; Bourret, 1942b; Liu, 1950: China; Kirtisinghe, 1957: Sri Lanka; Manthey and Grossmann, 1997: Peninsular Malaysia; Leong and Chou, 1999: Singapore; Ziegler, 2002: Vietnam); 4 (Chou and Lin, 1997; Taiwan, Republic of China); 6 (Yang, 1998: Taiwan, Republic of China; Chan-Ard, 2003: Thailand)

TABLE 1. Continued.

	Status of description
Hoplobatrachus sinensis	2 (Bourret, 1942a: Indo-China); 4 (Chou and Lin, 1997: Taiwan, Republic of China); 6 (Yang, 1998: Taiwan, Republic of China; Chan-Ard, 2003: Thailand)
Huia cavitympanum	1 (Yang, 1991: B; Malkmus et al., 2002: B); 2 (Inger, 1966: B; Matsui, 1979: B); 3 (Inger, 1985: B); 6 (Boulenger, 1893: B)
Ingerana baluensis	0
Limnonectes asperata	0
Limnonectes finchi	1 (Malkmus et al., 2002: B); 3 (Inger, 1985: B)
Limnonectes ibanorum	2 (Inger, 1966: B); 4, 5 (Inger, 1985: B)
Limnonectes ingeri	4, 5 (Inger, 1985: B)
Limnonectes kenepaiensis	0
Limnonectes kuhlii	1 (Schijfsma, 1932: Java, Indonesia; Dring, 1979: Peninsular Malaysia; Bourret, 1942a; Indo-China; Matsui, 1979; Leong and Chou, 1999: Singapore); 2 (Smith, 1917; Pope, 1931: Hainan, China; Bourret, 1942b; Inger, 1966: B; Manthey and Grossmann, 1997: B; Malkmus et al., 2002: B); 4, 5 (Inger, 1985: B); 6 (Yang, 1998: Taiwan, Republic of China)
Limnonectes laticeps	1 (Inger, 1985: B, association with parent species weak); 4 (Leong, 2004: Peninsular Malaysia)
Limnonectes leporinus	1 (Malkmus et al., 2002: B); 2 (Inger, 1966: B, as *Rana blythi*); 4, 5 (Inger, 1985: B, as *Rana blythi*)
Limnonectes malesianus	1 (Inger, 1985: B); 2 (Manthey and Grossmann, 1997); 4 (Leong and Chou, 1999: Singapore)
Limnonectes palavanensis	1 (Inger, 1956: B, as *Rana microdisca palavanensis;* Inger, 1985: B; Malkmus et al., 2002: B)
Limnnectes paramacrodon	0
Limnonectes rhacodus	0
Meristogenys amoropalamus	1 (Malkmus et al., 2002: B); 3 (Yang, 1991: B)
Meristogenys jerboa	0 (illustrations of *Staurois jerboa* in van Kampen, 1910, reproduced by Bourret, 1942b, based on specimens that are incertae sedis)
Meristogenys kinabaluensis	2 (Malkmus et al., 2002: B); 3 (Inger, 1985: B; Yang, 1991: B)
Meristogenys macrophthalmus	0
Meristogenys orphocnemis	1 (Malkmus et al., 2002: B); 3 (Yang, 1991: B)
Meristgenys phaeomerus	3 (Yang, 1991: B); 4, 5 (Inger, 1985: B)
Meristogenys poecilus	3 (Inger, 1985: B; Yang, 1991: B)
Meristogenys whiteheadi	1 (Malkmus et al., 2002: B); 3 (Yang, 1991: B); 6 (Boulenger, 1893: B)
Occidozyga baluensis	1 (Malkmus et al., 2002: B); 3 (Inger, 1985: B)
Occidozyga laevis	1 (Malkmus et al., 2002); 2 (Alcala, 1962: Negros, Philippines; Smith, 1916: Thailand; Bourret, 1942b: Thailand); 3 (Inger, 1985: B); 4 (Alcala, 1962: Negros, Philippines; Leong and Chou, 1999: Singapore)
Rana baramica	0
Rana erythraea	1 (van Kampen, 1910: Java, Indonesia; Smith, 1930; Bourret, 1942a: Indo-China; Bourret, 1942b; Inger, 1966: B; Malkmus et al., 2002); 2 (Leong and Chou, 1999: Singapore); 6 (Lim and Lim, 1992: Singapore); 7 (Manthey and Grossmann, 1997)
Rana glandulosa	0 (The description of the larval stages in Berry [1972] from Peninsular Malaysia, which has been reproduced by Inger [1985] and Manthey and Grossmann [1997] refers to *Rana banjarana* Leong and Lim [2003])
Rana hosii	1 (Bourret, 1942b; Inger, 1966: B); 2 (Manthey and Grossmann, 1997: Peninsular Malaysia; Malkmus et al., 2002)
Rana laterimaculata	0 (description in preparation by T.-M. Leong, pers. comm.)
Rana luctuosa	1 (Boulenger, 1912; Bourret, 1942a: Indo-China; Dring, 1979: Peninsular Malaysia; Inger, 1985: B; Malkmus et al., 2002); 2 (Bourret, 1942b: Thailand and Peninsular Malaysia; Inger, 1966; Manthey and Grossmann, 1997: Thailand and Peninsular Malaysia)
Rana nicobariensis	1 (van Kampen, 1923:226: Java, Indonesia; allocation to parent species tentative; Smith, 1930; Bourret, 1942a: Indo-China; Bourret, 1942b; Inger, 1956; Iskandar, 1998: Java and Bali, Indonesia; Malkmus et al., 2002); 2 (Schijfsma, 1932: Java, Indonesia)
Rana picturata	0 (may be confused with *Rana signata* in the literature)
Rana raniceps	1 (Boulenger, 1912: as *Rana labialis*; Bourret, 1942a: Indo-China: as *Rana chalconota;* Malkmus et al., 2002); 2 (Flower, 1896: Singapore: as *Rana chalconota*; Bourret, 1942b: Singapore: as *Rana chalconota*; Inger, 1966: B: as *Rana chalconota*; Manthey and Grossmann, 1997: Peninsular Malaysia: as *Rana chalconota;* Leong and Chou, 1999: Singapore); 4, 5 (Inger, 1985: as *Rana chalconota*)
Rana signata	2 (Inger, 1966: B; Manthey and Grossmann, 1997: B: figures may be a composite of *Rana signata* and *R. picturata*); 4, 5 (Inger, 1985: B, comments as for preceding entry)
Staurois guttatus	1 (Malkmus et al., 2002: B); 4 (Inger and Wassersug, 1990: B: species not identified, and referred to "centronelid–like anuran larva;" identified by Inger and Tan (1990) as *Staurois natator.* Inger's (1966) description of the larvae from Mindanao is based on the tadpoles of a non-conspecific species)

TABLE 1. Continued.

	Status of description
Staurois latopalmatus	0 (description purported to be of this species in Boulenger, 1893 is incertae sedis; that in Inger, 1966, possibly a larva of *Rhacophorus* sp., R. F. Inger, pers. comm.)
Staurois parvus	0 (possibly confused with *Staurois guttatus*)
Staurois tuberilinguis	1 (Malkmus et al., 2002: B); 4, 5 (Malkmus et al., 1999: B); 6 (Malkmus, 1999)
Rhacophoridae	
Nyctixalus pictus	1 (Inger, 1966: B); 2 (Manthey and Grossmann, 1997; Malkmus et al., 2002); 3 (Inger, 1985: B); 4 (Leong and Chou, 1999: Singapore)

In Painted Turtles (*Chrysemys picta*), variation in the degree of carnivory, water temperature, or growing season length are usually invoked as explanations for variation in life-history traits, such as individual growth rate and body size, within and between populations (Iverson and Smith 1993; Frazer et al. 1993; St. Clair et al. 1994). Painted Turtles are opportunistic predators and omnivorous as adults (Ernst et al. 1994). In creek, marsh, small pond, or lake habitats, painted turtles may ingest large quantities of plants and aquatic insect larvae and other aquatic arthropods (MacCulloch and Secoy 1983; Lindeman 1996; Rowe and Parsons 2000). In contrast, populations residing in relatively large riverine habitats may consume mainly invertebrates (Gibbons 1967; MacCulloch and Secoy 1983). A high protein, carnivorous diet may be responsible for relatively rapid growth rates and larger adult body size in some populations (Gibbons 1967; MacCulloch and Secoy 1983) and may be, in part, responsible for a positive correlation between latitude and body size (MacCulloch and Secoy 1983). Therefore, studies of dietary habits at both local and broad geographic scales may lend insights into geographic variation in life-history traits of Painted Turtles.

Midland Painted Turtles (*Chrysemys picta marginata*) of the Beaver Island Archipelago, in northern Lake Michigan, reside in inland lakes and wetlands, and in shallow Lake Michigan bays. We studied the dietary habits of Painted Turtles at Garden Island Harbor during two periods in 2001: 5–26 June (the early sampling period) and 3–12 August (late sampling period). Garden Island Harbor (GIH) is a shallow Lake Michigan bay in Charlevoix County, Michigan (45°47.90'N, 85°30.39'W) that is ca. 2 km N of Beaver Island. Garden Island is an uninhabited island in northeastern Lake Michigan and our study area is associated with an extensive lakeside marsh system located on the southwest portion of the island. Garden Island Harbor is about 1,300 x 700 m and, with its fringe wetlands, has a total surface area of about 100 ha. Maximum depth of GIH is about 5 m.

We found turtles in two aquatic habitats in the harbor: 1) relatively deep (1–2 m) and cool water (mean ± SD, range, water temperature at 2 m depth = 18.0 ± 3.10°C, 9.9–25.7°C, N = 1632 hourly samples recorded between 6 June and 12 August 2001 using Optic Stowaway data loggers, Onset Computer Corporation) where turtles were observed actively foraging, and 2) in relatively shallow (10–50 cm) and warm water (mean hourly water temperature at 50 cm depth = 21.6 ± 3.33°C, 13.4–30.1°C) while they were nestled, motionless, at the bases of bulrushes. We collected turtles by hand (75%) while wading or snorkeling or in fykenets (25%) placed at depths of 1.5–2 m. Of those turtles captured by hand, about 60% were collected in open water and the other 40% were collected among the bulrushes in the shallows. Upon capture, we determined the gender of the turtle, uniquely marked marginal scutes, measured mass to the nearest 10 g using a spring scale, and measured maximum straight-line carapace length (CL) to the nearest 1 mm using calipers.

Data on diet were obtained via stomach flushing. We restrained animals in a device modified from Fields et al. (2000) and anesthetized individuals using a dosage of 25 mg ketamine / kg body mass (Fields et al. 2000). After opening the turtle's mouth, we forced it to bite down on a rubber stopper and inserted a pediatric feeding tube (3 mm diameter) into the stomach. The tube was connected to a weed spray can that was modified to deliver water. Stomach contents were collected in a wire mesh strainer and subsequently preserved in 10% formalin. We later sorted each sample into taxonomic groups, dried each taxon individually in aluminum foil to a constant mass at 80°C, and then measured dry mass to the nearest 0.001 g. We attempted to count individual prey items from each stomach although partial digestion of items made this

impossible for some samples.

We calculated the frequency of occurrence of taxa (frequency of stomachs that contained a particular taxon) in the early and late sampling periods separately, and in males and females separately. Chi-square contingency analyses were used to make comparisons in frequencies of prey items between early and late sampling periods while accounting for differences in sample sizes between periods. Only one male was captured during the early period making comparisons of males and females possible only within the late period. We used the most frequently consumed prey items in statistical analyses such that the expected Chi-square values for a category were not less than five (i.e. caddisfly larvae, crayfish, snails, and plants) in order to maintain statistical validity of a Chi-square Goodness of Fit test (Zar 1996). Total mass percent was the total dry mass of a prey item type expressed as a proportion of the total dry mass of the sample. Because prey item densities are likely to exhibit temporal variation due to variation in life cycles of aquatic insects, we assessed temporal variation in diet that would affect an overall view of diet (Lindeman 1996). Since painted turtles are sexually dimorphic in size (females are larger than males), potential gender differences in diet were also evaluated because females may eat larger prey items than males (Cagle 1952; Shealy 1976). To assess potential differences in the mass of food consumed by male and female turtles, which could bias our results, we conducted an ANCOVA with CL as a covariate.

We obtained food items from 57 of 64 (89.1%) individuals that were stomach-flushed. During the June sampling period, 25 female turtles and one male turtle were collected. During August, food samples were obtained from 16 female and 15 male turtles. For individuals from which we obtained food samples, CL averaged 151.3 ± 12.91 mm and body wet mass averaged 433.9 ± 113.91 g.

Of the stomachs that contained food, plant matter was found in 25 of 57 (43.9%) stomachs while animal matter was found in 55 of 57 (96.5%) stomachs (Table 1). Of the stomachs that contained plant matter, fragments of Wild Celery (*Vallisneria americana*) were found in 38.5% with small fragments of unidentified plant fragments comprising the remaining fraction. The most frequently ingested animal items were crayfish (Decapoda), snails (Pulmonata), and caddisfly (Trichoptera) larvae. Counts per stomach of dragonfly (Anisoptera) and damselfly (Zygoptera) larvae were as high as 40. Counts per stomach of snail (Pulmonata) ranged from 40–100. Johnny Darters (*Etheostoma nigrum*) and Spot-tail Shiners (*Notropis hudsonius*) were the main vertebrate items. Neither seasonal (early vs. late period) or gender effects were significant ($P > 0.05$ in both Chi-square contingency analyses).

On a dry mass basis, animal matter comprised 97.2% of the total dry mass while plant matter represented only 2.8% (Table 1). Crayfish were the dominant prey items followed by snails, fish, and dragonfly larvae. There was no significant difference in the amount of dry mass consumed by males or females ($P > 0.05$ in an ANCOVA with gender as a main effect and CL included as a covariate).

Midland Painted Turtles at GIH were nearly carnivorous consuming mainly crayfish, snails, and caddisfly larvae. While other investigators have observed an animal matter bias in the diets of painted turtles (Hart 1982; MacCulloch and Secoy 1983; Lindeman 1996), such extreme proportions of dietary animal matter, such as that observed in our study, has not been reported previously. In other populations where turtles consumed mainly animal prey, arthropods (crayfish, insect larvae, or scuds) were common dietary items (MacCulloch and Secoy 1983, Lindeman 1996). Other studies have reported almost herbivorous diets (Gibbons 1967) or nearly equal volumes of plant and animal material (Lagler 1943; Ernst and McDonald 1989; Rowe and Parsons 2000). Differences in diet among Painted Turtle populations are likely to be in part because of differences in prey availability. For instance, Painted Turtles that were sampled throughout the summer months over a two-year period at Miller's Marsh on neighboring Beaver Island (Rowe and Parsons 2000) were found to consume large quantities of Yellow Lily (*Nuphar variegatum*) fruit, which does not occur at GIH. Conversely, Spot-tail Shiners and Wild Celery, which were fairly common in the diets of Painted Turtles at GIH, do not occur at Miller's Marsh.

TABLE 1. Dietary composition of 57 Painted Turtle (*Chrysemys picta*) stomachs from Garden Island Harbor, Michigan.

Item	Frequency of occurrence (% of stomachs that contained an item)	Total mass %
Crustacea		
Decapoda (A)	39 (68.5)	42.840
Amphipoda (A)	4 (7.0)	0.120
Insecta

Acknowledgments.—Thanks are extended to J.C. Gillingham and Central Michigan Biological Station for laboratory space and logistic support. The efforts of D. Breen, P. Rowe, and C. Zurenko made data collection possible. Turtles were collected under a permit issued to J. C. Gillingham (Michigan Department of Natural Resources Cultural and Scientific Collectors Permit # CA341) and turtles were handled according to IACUC standards (approval number 02-07) issued by Central Michigan University.

Understanding species-habitat associations are imperative for wildlife management (Cross and Petersen 2001). Although several causes of global amphibian declines are suggested, habitat modification is implicated in many cases (Daniels 1991; Fisher and Shaffer 1996; Lips 1998, 1999; Richards et al. 1993). Because amphibians show site fidelity and have limited dispersal capabilities, forest fragmentation and modification could effectively disrupt their population structures (Marsh and Pearman 1997; Osawa and Katsuno 2001) and cause local extinctions of species (Blaustein et al. 1994). For example, frogs belonging to the genus *Leptodactylus* have been reported to be more abundant in larger patches of forest than in smaller patches (Marsh and Pearman 1997). In particular, amphibian populations relying on forest microhabitat features might undergo rapid decline because of disturbances.

Because of the rapid conversion of Indian forests to plantations, the status of Indian forest amphibians is of concern (Daniels 2003; Reddy et al. 2002). In south India, forest practices have modified the once contiguous forests of the Western Ghats into fragments resulting in isolation of habitats, disrupted microhabitat and altered vegetation structure. However, information on Indian amphibians is sparse (Oommen et al. 2000). Among Indian frogs, Bull Frog (*Hoplobatrachus tigerinus*) populations appear to have declined from paddy fields (pers. obs.). This might be due in part to the export of frog legs (now banned) and the application of insecticides and pesticides used in rice cultivation (Mohanthy-Hejmadi and Dutta 1981). Reports have indicated a threat by habitat fragmentation to torrent frogs of the genera *Nyctibatrachus* and *Melanobatrachus* (Gupta 1998). Surveys in modified habitats have recorded complete absence of several species of the genus *Micrixalus*, although they are present in the adjoining forest habitats (Daniels 2003; Krishna et al. 2005). The disturbed sites of Kudremukh National Park in the central Western Ghats have shown a 50% reduction in amphibian species richness when compared to undisturbed forest sites (Krishnamurthy and Hussain 2004).

We examined forest habitat associations of the Bicolor Frog, *Clinotarsus curtipes* (Ranidae, Hyloraninae) in three habitat types: native forest, coffee and cardamom plantations. This frog breeds in streams and ponds with tadpoles occupying aquatic habitats for over a year, after which frogs inhabit the litter and rock crevices in forest floors of the Western Ghats, South India (Daniel 2002). Our results provide insights to the potential effects of native forest conversion to plantation on this species.

HERPETOLOGICAL REVIEW

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2005 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ssarherps.org/pages/membership.html.

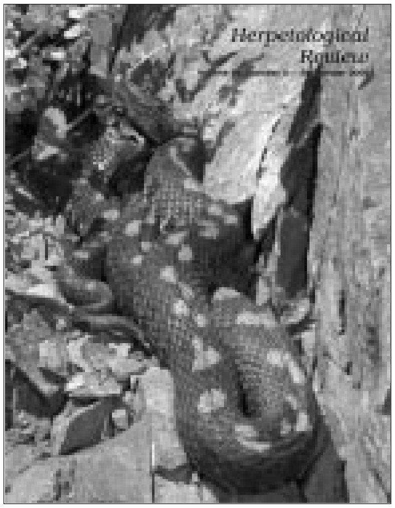
All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with VISA or MasterCard (account number and expiration date must be provided). Payment should be sent to: Theodora Pinou, SSAR Treasurer, Department of Biological & Environmental Sciences, Western Connecticut State University, 181 White Street, Danbury, Connecticut 06810, USA. Fax: (203) 837-8769; e-mail: PinouT@wcsu.edu.

Future Annual Meetings

2006 — Site pending, 12–17 July (with ASIH, HL)
2007 — Saint Louis, Missouri (with ASIH, HL)

About Our Cover: *Vipera raddei*

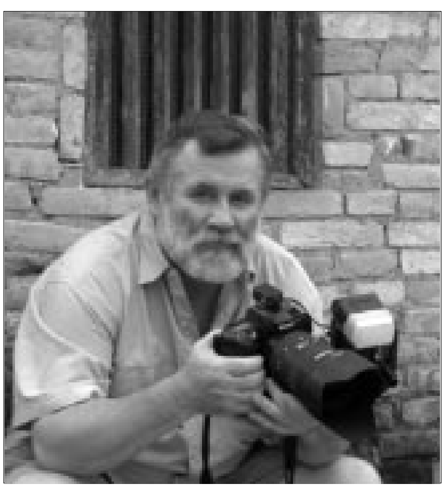


The *Vipera xanthina* complex comprises eight species according to recent treatments (Nilson et al. 1999; Kaupia. Darmstädter Beiträge zur Naturgeschichte, Heft 8, 1999:99–102; Ananjeva et al. 2004. Colored Atlas of Reptiles of the North Eurasia: Taxonomic Diversity, Distribution, Conservation Status. St. Petersburg, 2004: 230 pp.) allocated to the subgenus *Montivipera*: *xanthina, bornmuelleri, bulgardaghica, albizona, wagneri, raddei, albicornuta,* and *latifii*. The Armenian Viper, *Vipera (Montivipera) raddei raddei* Boettger, 1890 is distributed in the southern regions of Armenia and Nakhichevan (Azerbaijan) as well as in adjacent regions of Turkey and Iran. *V. r. kurdistanica* Nilson & Andrén, 1986, is known from northeastern Iran to Lake Urmia.

The cover image depicts *V. raddei*, a rare, narrowly endemic and declining species included in the Red Lists of Armenia (1987) and the former USSR (1984) (see Jeff Ettling's article in this issue [p. 231] of *Herpetological Review* describing current conservation-oriented field research on this species). It occurs at elevations of 1000 to 2700 m in xerophytic montane associations, in particular oak forests and open juniper woodlands, favoring rocky slopes with sparse brush cover. The distribution pattern in the southern spur ranges of the Lesser Caucasus reflects the mosaic of suitable habitats in this region.

The cover photo was taken by **Nikolai L. Orlov**, who found and photographed the basking snake in situ in the morning among rock outcrops, 2300 m elevation, in the Megri District of southern Armenia. This population, first discovered in 2004, is associated with a rocky subalpine meadow. The snakes here appear to differ from those elsewhere by their darker coloration. Orlov used a tripod-mounted Fujifilm FinePix S2 Pro digital camera, with a Nikkor 60mm f2.8 macro lens, capturing the image using available light.

Orlov, who has authored more than 160 publications, is a senior research scientist in the Department of Herpetology, Zoological Institute, Russian Academy of Sciences (Saint Petersburg, Russia; http://www.zin.ru/labs/herplab/index.html). His interests focus on the herpetofauna of Palearctic and Oriental Asia: biodiversity, biogeography, ecology, taxonomy, phylogeny, conservation, and captive breeding.



SSAR BUSINESS

Seibert Award Winners for 2005 Announced

The 14th annual Seibert Awards were presented at the 48th Annual Meeting of the SSAR in Tampa, Florida, 5–12 July 2005. These awards are named in honor of Henri C. Seibert, an early and tireless supporter of SSAR (having served as an officer for over 20 years). In recognition of outstanding student presentations at the annual meeting, a single award was given in each of the following categories: Physiology/Morphology (5 eligible presentations), Evolution/Systematics (5 eligible presentations), Ecology (16 eligible presentations), and Conservation (9 eligible presentations). All four awardees will receive a check for US $200 and a book from Chuck Crumly at the University of California Press.

The Winners—Physiology/Morphology: **Diana Andres**, Rod Mackie, Steve Secor, and Bobby Espinoza, Cal State University, Northridge; University of Illinois, Urbana-Champaign; University of Alabama, Tuscaloosa, "The grass *is* greener: Costs of diet switching may inhibit insect eating by herbivorous reptiles." Ecology: **Deborah Hutchinson**, Frank Schroeder, Alan Savitzky, Akira Mori, Jerrold Meinwald, and Gordon Burghardt, Old Dominion University; Cornell University; Kyoto University; University of Tennesee, "Chemical evidence for sequestration of defensive toxins in the Asian snake *Rhabdophis tigrinus* (Colubridae: Natricinae)." Conservation: **Kristen Bell** and Maureen Donnelly, Florida International University, "Influence of forest fragmentation on community structure of frogs and lizards in lowland Costa Rica." Evolution/Systematics: **Daniel Moen**, Stony Brook University, "Cope's Rule in cryptodiran turtles: Do extant species reflect a trend of phyletic size increase?"

Honorable Mention—Physiology/Morphology: **Sean Graham**, Matthew Grober, and Gordon Schuett, Georgia State University, "Seasonal timing of the mating period in cottonmouths (*Agkistrodon piscivorus*): Evidence from sex steroids, urogenital tract histology, and male sexual behavior." Ecology: **Michael Benard**, University of California, Davis, "Survival trade-offs between two predator-induced phenotypes in Pacific treefrogs (*Pseudacris regilla*)." Conservation: **Brian Todd**, Betsie Rothermal, and Whit Gibbons, Savannah River Ecology Lab, "Forest clearing reduces growth and survival of recently metamorphosed southern toads (*Bufo terrestris*)." Evolution/Systematics: **Tom Devitt**, University of California, Berkeley, "Phylogeography of a ring species: The *Ensatina eschscholtzii* complex revisited."

The judges were Chuck Crumly (University of California Press), Bobby Espinoza (California State University, Northridge), David Hardy, Sr. (Tucson, AZ), Kirsten Nicholson (Washington University), Charles Peterson (The College of New Jersey), Marion Preest (The Claremont Colleges), and Stephen Richter (Eastern Kentucky University).

Grants-in-Herpetology: Annual Report (2005)

An award in the amount of US $500 was made to each of the

following individuals:

Conservation.—**Jodi Rowley**, James Cook University. Project title: "Uncovering the secret lives of frogs. Why some frogs are declining from a fatal disease and others are doing just fine."

Field Research.—**Dean A. Croshaw**, University of New Orleans/Savannah River Ecology Laboratory. Project title: "Polyandry in *Ambystoma talpoideum* and its consequences for individuals and populations."

Laboratory Research.—**Sean Graham**, Georgia State University. Project title: "Endocrine regulation of the mating season in cottonmouths (*Agkistrodon piscivorus*): Evidence from sex steroids, urogenital tract histology, and male sexual behavior."

Herpetological Education.—**David Wojnowski**, Kent State University. Project title: "Project SAVE (Saving Africa's Vital Ecosystems)."

Travel.—**Juan M. Guayasamin**, University of Kansas. Project title: "Phylogenetic relationships of Glass Frogs (Anura: Centrolenidae)."

International.—**Jennifer Germano**, University of Otago, New Zealand. Project title: "How do homing capabilities affect the success of translocations of *Leiopelma pakeka*?"

Bibliograhic Research.—**Keith A. Metzger**, State University of New York-Stony Brook. Project Title: "A comprehensive literature survey of lepidosaur diets."

2005 Grants-in-Herpetology Committee.—Chair: Erik R. Wild. Reviewers: Jeffrey Parmelee, Tiffany M. Doan, Craig E. Nelson, Kirsten Nicholson.

SSAR congratulates the 2005 GIH recipients and thanks the committee members for their efforts.

Grants-in-Herpetology 2006 Proposals

Proposals are now being accepted for the 2006 SSAR Grants-in-Herpetology Program. This program is intended to provide financial support for deserving individuals or organizations involved in herpetological research, education, or conservation. Application deadline is 31 December 2005. Grant application details are available at:

<http://www.ssarherps.org/pages/GIH.html>

NEWSNOTES

Florida Turtle Conservation Trust Launches New Website (www.ftct.org)

The Florida Turtle Conservation Trust (FTCT) was formed in 1999 by a group of Florida biologists and conservationists concerned with the conservation outlook for Florida turtles. Our purpose is to promote the conservation of all Florida turtle species and the preservation of intact, free-ranging populations and their associated ecosystems throughout the state of Florida. The FTCT is committed to and supports education, conservation, research, and management efforts with the above goals in mind.

Florida is home to over 8% of the world's known turtle species and is a significant area for both turtle diversity and habitat. Twenty-five of the 54 turtle species found in the United States also occur in Florida. They are represented in upland communities, such as scrub and sandhill, in rivers, lakes, swamps, and even coastal habitats, such as salt marsh, mangrove communities and marine systems. Certainly, habitat diversity and species richness makes Florida a chelonian hotspot.

The FTCT focuses its efforts on the conservation of non-marine species. This work is accomplished independently or in partnership with agencies and other non-governmental organizations. To date, the FTCT has:

- organized and co-sponsored a symposium on the status and conservation of Florida turtles;

- co-sponsored a national workshop on the ecology, status and conservation of diamondback terrapins;

- initiated the development of both a national and Florida Diamondback Terrapin Working Group;

- partnered with the Gopher Tortoise Council on a project that distributed an educational book to nearly 3,000 elementary school libraries throughout the range of the gopher tortoise;

- partnered with the Gopher Tortoise Council on a project that distributed an educational slide/PowerPoint presentation and supplemental resource notebook to educators throughout the range of the gopher tortoise;

- co-developed and funded the Pinellas County School District's Florida turtle track pack;

- organized Florida turtle educational exhibits at nature festivals and environmental events;

- and assisted the Florida Fish and Wildlife Conservation Commission with the development of a diamondback terrapin educational poster and exhibit.

Members of the FTCT include biologists, land managers, agency representatives, environmental consultants, educators, conservationists, and concerned citizens. In addition to supporting conservation work, members receive discounts on meeting registration fees and opportunities to attend organized field trips. For more information please visit www.ftct.org.

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (rwh13@csufresno.edu) well in advance of the event.

7–9 October 2005—Gopher Tortoise Council Annual Meeting, Palatka, Florida, USA. Information: www.gophertortoisecouncil.org.

21–23 October 2005—Snakebites in the New Millennium Symposium, University of Nebraska Medical Center, Omaha, Nebraska, USA. Information: http://app1.unmc.edu/cce/snakebites/

5–6 November 2005—Kansas Herpetological Society Annual Meeting, Pittsburg State University, Pittsburg, Kansas, USA. Information: http://www.ku.edu/~khs/AnnualMeetingInfo.html.

31 March–2 April 2006—Symposium—Conservation and Herpetology: The Middle American Connection. Miami-Dade College, Miami, Florida, USA. Information available from Larry David Wilson, organizer, by e-mail: lwilson@mdc.edu. See additional information on p. 352 of this issue.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **María del Rosario Castañeda** or **Michele Johnson**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can be found at: http://www.herplit.com/contents.

Comparative Analysis Of Morphological Characters Associated With Arboreality And Orthinophagy In Snakes

Several morphological characters are correlated with diet and habitat use. In snakes, gape size and relative head length are correlated with maximum prey size, while arboreal habits are associated with tail length, body size and heart position. The insular endemic pitvipers *Bothrops insularis* (SE Brazil) and *Gloydius shedaoensis* (NE China) are under similar selective pressures not shared by their mainland closest relatives. On islands, adults of both species have an almost exclusively avian diet (while mainland species feed on mammals), and show an increase in arboreality relative to mainland relatives. The authors compared morphological characters associated with dietary habits and arboreality between mainland and insular *Bothrops* and *Gloydius* species and assessed phylogenetic relationships between *B. insularis* and mainland species. Results show that both *B. insularis* and *G. shedaoensis* have significantly longer heads and smaller litter sizes than mainland relatives. However, body size, tail and fang length, and heart position only differ between *B. insularis* and mainland relatives. The authors suggest caution, in the absence of multiple studies on single species, when interpreting character changes related with shifts in selective pressures.

Wüster, W., M. R. Duarte, and M. D. G. Salomão. 2005. Morphological correlates of incipient arboreality and ornithophagy in island pitvipers, and the phylogenetic position of *Bothrops insularis*. Journal of the Zoological Society of London 266:1–10.

Comparison of Flying Performance in *Draco* Lizards

Previous studies on flying lizards of the genus *Draco* found an isometric relationship between wing area and body mass, even though there is significant intraspecific variation in body size. Based on this isometric pattern and on aerodynamic theory, the authors hypothesized that smaller species would perform better at gliding than larger species. Within the genus, larger body size has evolved independently several times, with larger species occurring in lineages found in sympatry with other *Draco* species. Additionally, none of the single-species communities is composed of a large-bodied species. The authors' objective was to establish a possible association between body size and locomotor performance evolution. To test for gliding performance, trials were conducted using separate takeoff and landing poles of known height and distance from each other. Maximum velocity (adjusted for wind velocity and direction), total height lost during the glide, and total glide angle were estimated based on trial videos. Data was collected for 11 species covering the range of body sizes in the genus and independent contrasts were calculated to correct for phylogenetic autocorrelation. Results agree with the predictions: smaller species have higher velocity, lose less altitude and have smaller angles during glides. Furthermore, results support gliding performance in *Draco* lizards can be estimated from morphological data alone. The authors discuss the ecological implications of larger size and its apparent fitness cost overcome only in the presence of other flying lizards.

McGuire, J. A., and R. Dudley. 2005. The cost of living large: comparative gliding performance in flying lizards (Agamidae: *Draco*). The American Naturalist 166:93–106.

Sea-Level Rise Impact On Turtle Nesting Habitat

One of the inevitable consequences of global warming is an increase in sea-level. To estimate the impact on turtle nesting habitat, the authors measured individual beach profiles and developed elevation models using geographic information systems. Fieldwork was done in Bonaire, Netherlands Antilles, where four species of turtles nest: *Eretmochelys imbricata, Caretta caretta, Chelonia mydas*, and *Dermochelys coriacea*. Data on potential turtle nesting sites collected from 1993 to 2000 was used to estimate relative nesting use of different beaches. Three different sea-level rise scenarios were considered: 0.2, 0.5 and 0.9 m, which represent the full range of potential sea-level rise estimated by the Intergovernmental Panel on Climate Change (2001). Associations between physical characteristics (length, width, slope, elevation, aspect, and land use behind the beach), nesting activity and flooding vulnerability were estimated. Potential nesting area was estimated based on the preferred elevation range for *E. imbricata* and *C. caretta.* Results show that nesting activity was correlated with beach slope, with steeper beaches more frequently used. Based on

the models, 14% of the total beach would be lost to inundation with a 0.2 m sea-level increase; 31% and 50% would be lost with 0.5 and 0.9 m rises, respectively. No relationship was found between nesting activity and vulnerability, or between nesting activity and land use behind the beach. With a 0.2 m sea-level rise, preferred nesting areas for *E. imbricata* and *C. caretta* would decrease 11%; the decrease would be 41% and 21% with a 0.5 and 0.9 m sea-level rise respectively. Even though it is difficult to anticipate the effect of sea-level rise on turtle nesting habitat and to predict female response to the rise, estimations that allow identification of vulnerable areas are necessary for future coastal management decisions.

FISH, M. R., I. M. CÔTÉ, J. A. GILL, A. P. JONES, S. RENSHOFF, AND A. R. WATKINSON. 2005. Predicting the impact of sea-level rise on Caribbean sea turtle nesting habitat. Conservation Biology 19:482–491.

Effects of Early Evolutionary History in Present-Day Ecology

Two main theories on the origin of ecological traits have been proposed: 1) the 'deep history hypothesis,' which states that differences in ecological traits among species arose early in the evolutionary history of clades and that present day assemblages are based on those preexisting differences, and 2) the 'competition hypothesis,' which argues that niche differentiation occurred in relatively recent ecological time, resulting from shifts in prey availability, competition, or dietary preferences. The authors combined phylogenetic and ecological data to reconstruct the evolution of dietary shifts in squamates and test two predictions consistent with the 'deep history hypothesis': 1) the presence of a strong relationship between diet and phylogeny and 2) the ability to identify nodes in which dietary shifts have occurred. One hundred and eighty-four species, of 12 families, were included in the analysis. Two phylogenetic hypotheses were considered, a composite tree reflecting the traditional view and a recently proposed alternative (Townsend et al. 2004). Canonical correspondence analysis was used to measure the association between dietary composition and phylogeny, and to identify points of diet divergence in squamates. Results show a strong relationship between diet and evolutionary history, and significant dietary shifts in Iguania/Scleroglossa, Agamidae/Iguanidae, Scincidae, Varanidae, Gymnophthalmidae, and Teiidae. Results also suggest deep history has played an important role in lizard diet specification and could account for the actual niche partitioning in communities of non-closely related species. However, authors also point out that although present-day differences have 'ancient roots', current interspecific interactions still have a strong influence on present assemblages. Traits associated with dietary and other ecological shifts in squamates are also discussed.

Colonization Patterns of Beta *Anolis* (*Norops*) Lizards

The lizard genus *Anolis* is distributed from southeastern North America, to tropical South America, including Central America and the West Indies. The traditional view suggests that West Indian species represent over-water dispersal from a mainland ancestor with subsequent inter-island colonizations. The focus of this study is the highly diverse mainland clade *Norops* (or Beta section), which recent analyses have suggested is derived from a West Indian ancestor. Highly successful island-to-mainland colonizations are particularly rare. The authors included mitochondrial ND2 (189 spp., *Norops* and non-*Norops*), and nuclear ITS-1 (51 spp., *Norops*) sequences. Phylogenetic analysis included parsimony and Bayesian methods. The ancestral state reconstruction (mainland or West Indian) was performed on the mitochondrial-only tree, using a Bayesian tree-sampling technique (Pagel and Lutzoni 2002). Additionally, Wilcoxon signed-ranks and Shimodaira-Hasegawa tests were performed to test alternative relationships within the *Norops* clade. A West Indian *Norops* ancestor was reconstructed in all trees, as well as a mainland ancestor in the node that leads to all mainland species. The combined analysis (ND2 and ITS-1) of *Norops* reconstructs three geographically circumscribed clades: Cuba, Jamaica, and Mainland. The Jamaica and Mainland clades are recovered as sister taxa, to the exclusion of the Cuban clade, supporting the hypothesis of mainland *Norops* being nested within a West Indian group. Alternative reconstructions were rejected by the Shimondaira-Hasegawa test but not by the Wilcoxon signed-ranks test. The authors discuss alternative scenarios, and particular characteristics of West Indian *Anolis* communities that might have promoted this successful island-to-mainland colonization.

Effects of Inactivity in Skeletal Motor Nerve Terminals in *Cyclorana alboguttata*

The authors studied the effects of prolonged inactivity associated with aestivation on neuromuscular transmission in the burrowing frog *Cyclorana alboguttata*. This species lives in semi-arid environments and is active for short periods of time after heavy precipitation. Between active periods, frogs burrow underground and experience a metabolic depression. To measure the effects of inactivity, the authors compared the structure and function of neuromuscular junctions on the iliofibularis muscle between active individuals and individuals that had been aestivating for 6 months. Structure variables included number, shape and length of primary, secondary and tertiary neuron branches. Function measurements included end-plate potentials (EPPs), miniature end-plate potentials (MEPPs), and resting membrane potential (RMP). EPPs and MEPPs were used to calculate quantal content (number of acetyl-

choline vesicles released per synapse by the nerve), quantal size (response of the muscle to the spontaneous release of a single synaptic vesicle), mean probability of transmitter release and number of active release sites. No significant differences were found between active and aestivator individuals in terminal structure, RMP or MEPPs. However, in the aestivating group the mean amplitude of induced EPPs significantly decreased and the proportion of nerve stimulations that failed to induce an EPP significantly increased. Quantal content was significantly higher in active frogs; in aestivating frogs there was a significant reduction in the probability of transmitter release and in the number of active release sites. Comparisons with previous studies on anurans and mammals are presented. In addition, characteristics of *C. alboguttata* physiology of aestivation and potential mechanisms of nerve preservation are discussed.

HUDSON, N. J., N. A. LAVIDIS, P. T. CHOY, AND C. E. FRANKLIN. 2005. Effect of prolonged inactivity on skeletal motor nerve terminals during aestivation in the burrowing frog, *Cyclorana alboguttata*. Journal of Comparative Physiology A 191:373–379.

Foraging Mode of *Bradypodion pumilum* and the Foraging Mode Dichotomy

Two foraging strategies, sit-and-wait and active, have been well accepted in lizard ecology. Other life history characteristics (e.g., type of prey, home range size, clutch size, daily energy expenditure) are associated with foraging mode, making the distinction a useful organizing concept. Due to the taxonomic bias and small taxon sampling, recent studies have questioned the validity of this partition. The author studied time budget and foraging mode in the chameleon *Bradypodion pumilum*, which represents a highly derived taxon difficult to classify, since it possesses traits that belong to each of the foraging modes. Association between levels of activity and sex, age, time of day and ambient temperature were assessed and lag-sequential analysis was applied to test for nonrandom association between foraging behavior and behaviors preceding it. In addition, the author presents an interspecific analysis of foraging mode using discriminant function analysis (DFA) on number of movements per minute (MPM) and percent time moving (%TM) data from the literature. The resulting discriminant function classified *B. pumilum* as an active forager. DFA results support the traditional cutoff values for classification of foraging modes (sit-and-wait foragers %TM < 15 and MPM < 1.0). Finally, the author comments on the intraspecific variability in foraging behavior, the value of the sit-and-wait and active forager dichotomy, and the utility of DFA to support this distinction.

BUTLER, M. A. 2005. Foraging mode of the chameleon, *Bradypodion pumilum*: a challenge to the sit-and-wait versus active forager paradigm? Biological Journal of the Linnean Society 84:797–808.

Evaluating the Impact of Trade on Wild Populations

The increasing trade of amphibians and reptiles has raised questions of whether this trade is affecting wild populations' survival and if it is contributing to the global amphibian and reptile decline problem. The authors review data on US shipments of amphibians and reptiles from 1998 to 2002 from the United States Fish and Wildlife Service (USFWS) Law Enforcement Management Information System (LEMIS). The authors found that the vast majority of the imported and exported species are for commercial use, including food, pets and traditional medicine, and that more than a million individuals, body parts, and products are shipped across the US borders every year. Most of the shipments are declared as wild caught with a significant amount of the records registered at or above the genus level, that is, with no species-specific information. Additionally, several species might be considered particularly vulnerable when trade volume is compared with biological characteristics and geographic distribution. Species with wide ranges, high densities and high reproductive productivity may be able to tolerate intensive collecting. Although the data do not confirm active unsustainable collection, it does provide information on the large volume of animals taken from the wild, the deficiencies of the LEMIS system, and the necessity for stricter regulations to prevent overcollecting.

Origins and Phylogenetic Relationships of Lissamphibia

Relationships among living amphibians (Lissamphibia) have been difficult to resolve, in part due to the large gap in time and morphology between fossils and extant forms. As a reflection of this ambiguity, there is still controversy about lissamphibian origins and whether the group is monophyletic. To address these questions, the authors sequenced 8 mitochondrial genomes of living amphibians and combined them with previously published genomes of amphibians (6 spp.) and other vertebrates (6 spp.). Phylogenetic reconstructions were performed using parsimony, maximum likelihood, neighbor-joining and Bayesian analyses. Alternative phylogenetic hypotheses within Lissamphibia were tested using approximately unbiased (AU) and Shimodaira-Hasegawa (SH) tests. Bayesian molecular dating that allows for an estimation independent of a molecular clock was used to calculate divergence times for major groups. Results from all phylogenetic approaches support the monophyly of Lissamphibia and Batrachia (Anura and Caudata). Alternative reconstructions rendering Lissamphibia paraphyletic and Anura and Gymnophiona as sister taxa were rejected by AU and SH tests. However, the Caudata sister to Gymnophiona hypothesis was not rejected. Additionally,

the authors tested the compatibility of their molecular time estimates with fossil time estimates on three alternative hypotheses: Lissamphibia is monophyletic with 1) Temnospondyli as sister group, or 2) Lepospondyli as sister group, and 3) Lissamphibia is not monophyletic, with Gymnophiona related to Microsaura (Lepospondyli), and Batrachia related to Temnospondily. Results support the hypothesis of lissamphibian monophyly with Temnospondyli as sister group. Finally, the potential geographic origins of each group are discussed, considering current distributions, plate tectonics, clade ages, and fossil record.

ZOO VIEW

"Vipers should cover the world like Sherwin-Williams paint."—Joe Laszlo explaining why his viper collection at the San Antonio Zoo was so large.

During the 1980s, one of the finest collections of living true vipers ever assembled was at the San Antonio Zoological Gardens where Jozsef (Joe) Laszlo was curator. Through Joe's efforts, the Zoo became recognized as a place where a number of viperid taxa rarely seen could be appreciated. His contribution to our understanding of the captive management of European vipers was critical. Laszlo was certainly a pioneer in focusing on husbandry issues, and the International Herpetological Symposium (IHS) issues an annual award in his name to a person who significantly contributes to captive management. When he died unexpectedly in 1987, his loss cast an unbelievable gloom in the zoo community; he was truly beloved. Joe was my first herpetological friend to die and I still miss him. See Murphy (1988. Herpetol. Rev. 19:5–6) and Card and Murphy (2000. SSAR Herpetol. Circ. No. 27:1–44) for details of his life and contributions to herpetology.

Joe's office was in the center section of the reptile building. Piles of reprints, correspondence, and handwritten notes littered his desk. To breed vipers, Laszlo was convinced that the interface between temperature and light was important for success. The off-exhibit area being small, he was unable to build a spacious hibernaculum to cool his temperate zone vipers so he installed a soft drink cooler instead to house the animals. Banks of fluorescent lights were suspended everywhere with an array of different bulbs which he was testing. Racks of shoe boxes and terrariums held a bewildering assortment of vipers. Joe was sure to call whenever he acquired any new viper, especially from Europe, and I still remember his excitement and enthusiasm when his first Armenian vipers (*Montivipera raddei*) came to the Zoo.

FIG. 1. Example of human allometric scaling and poor grooming. Joe Laszlo (left) and James Murphy in 1982. Photo courtesy of Bert Langerwerf, modified by David T. Roberts.

Today, Joe would be proud of the advances in our understanding of viperid biology and particularly impressed with the multifaceted program described in the following article by curator Jeff Ettling at the St. Louis Zoo. However, Laszlo would be saddened to discover that the wild population of this beautiful snake in Armenia have declined nearly 90% in approximately twenty years.

New Books and Papers

For captive managers, two new books have surfaced which are useful for ensuring proper sex ratios for the charges in the collection. The first is edited by Nicole Valenzuela and Valentine A. Lance and the title is *Temperature-Dependent Sex Determination in Vertebrates* (2004. Smithsonian Books, Washington DC; ISBN:1-58834-203-4). Lance was a reproductive physiologist at the Center for the Reproduction of Endangered Species (CRES) at the San Diego Zoo for many years. The book is organized into four sections: Prevalence of Temperature-Dependent Sex Determination of Vertebrates; Thermal Effects, Ecology, and Interactions; Evolutionary Considerations; and Conclusions: Missing Links and Future Directions. The second book is *Reptilian Incubation: Environment, Evolution and Behaviour*, edited by D. C. Deeming (2004. Nottingham University Press, Nottingham UK; ISBN:1-897676-11-5).

The Wildlife Conservation Society, headquartered at the Bronx Zoo, has published a book relevant to the Asian chelonian crisis. The authors are Win Maung and Win Ko Ko and the book is *Turtles and Tortoises of Myanmar* (2002. Wildlife Conservation Society, Yangon).

In 1829, Edward Turner Bennett wrote a fascinating book called *The Tower Menagerie: Comprising the Natural History of the Animals Contained in that Establishment, with Anecdotes of Their Characters and History. Illustrated by Portraits of Each, Taken from Life, by William Harvey, and Engraved on Wood by Branston and Wright.* The London Tower Menagerie (1245–1832) was not an ideal facility for reptiles but at various times over a span of nearly 600 years, the anaconda (called *Python Tigris* Var. by Bennett, likely Ceylonese pythons, *Python molurus pimbura*), over 100 rattlesnakes (called *Crotalus horridus*), and the alligator (called *Crocodilus lucius*) lived in the Tower. The Indian boa (called *Python Tigris*) laid a clutch of eggs which did not hatch. An interesting new book about the long history of the Royal Collection of Wild and

FIG. 2. Illustration of American Alligator (*Alligator mississippiensis*) living in Royal Menagery, Tower of London from Robert Huish's "The Wonders of the Animal Kingdom Exhibiting Delineations of the Most Distinguished Wild Animals in the Various Menageries of the Country" in 1830. Alligators and crocodiles are described as follows: "Living, as it were, in the confines of both land and water, these enormous animals extend their dominion equally over the inhabitants of both elements. Here they enjoy an absolute rule, and dread none of the common dangers which assault other less powerful animals." Bennett's specimen was said to be young, measuring not more than three feet in length, did not grow for two years, and was fed raw beef weekly which may be why the head seems abnormally small. Credit: Courtesy of Smithsonian Institution Libraries, Washington, DC.

Ferocious Beasts kept at the Tower Menagerie has been written by Daniel Hahn — *The Tower Menagerie* (2004. Jeremy P. Tarcher/Penguin, New York; ISBN:1-58542-335-1).

Workers with herps may not have considered the opportunity to see play in their animals. Gordon Burghardt has just published a comprehensive book called *The Genesis of Animal Play. Testing the Limits* (2005. MIT Press, Cambridge, Massachusetts; ISBN:0-262-02543-4). There are many references to play behavior in lower vertebrates, including an intriguing observation on possible play in amphibians by Kevin Zippel. Full disclosure: the African cichlid (*Tropheus duboisi*) playing with a submersible thermometer on the dust jacket lived in my home aquarium for many years. Many days I would hear this strange tapping noise and finally realized that the fish was hitting the side of the tank with the thermometer. I was reluctant to mention it to Gordon at first for fear of being labeled a lunatic hearing strange noises.

Jack Frazier has been a Smithsonian Research Associate based at the National Zoo's Conservation and Research Center in Front Royal, Virginia for many years. Jack is a major player in sea turtle conservation. It was gratifying to see that his commitment to their protection has been recognized in a terrific new book by James R. Spotila (*Sea Turtles. A Complete Guide to Their Biology, Behavior, and Conservation*. 2004. The Johns Hopkins University Press, Baltimore and London; ISBN: 0-8018-8007-8, p. 84). In 1997, Jack published a paper which is relevant to zoo biologists ("Sustainable development: modern elixir or sack dress?" Environ. Conserv. 24:182–193). The five central arguments of this paper are: (1) the expression has tremendous popularity and the term "sustainable" has appeared in countless contexts for decades; (2) although it is undefined, the term "sustainable development" is often used in so-called scientific discourse; (3) from the context in which it is used it routinely refers to continual growth (like cancer); (4) a major danger in its persistent use is that people who should be considering the concept carefully, consent its use in order to have social recognition and access to grants, etc.; (5) an attempt to attain continual growth cannot be consistent with biological conservation, whether considered as biological diversity or as ecological services.

Hans-Werner Herrmann, former herpetological curator at the Cologne Zoo and researcher with CRES, has published two papers in 2004: "A new frog species of the genus *Cardioglossa* from the Tchabal Mbabo Mtns, Cameroon (Anura: Arthroleptidae)" [Herpetozoa 17:119–125]; "Anuran habitat selection and temporal partitioning in a montane and submontane rainforest in Southwestern Cameroon—first results" [Salamandra 40:239–260].

In my last column (see p. 102), I noted the availability on CD of several Powerpoint presentations concerning herpetology. In order to simplify the acquisition of these programs, the permissions officer at Smithsonian Intitution Libraries has agreed that recipients can keep them permanently rather than having to return them as I communicated earlier.

Saint Louis Zoo Wildcare Institute: Center for Conservation of Near East Mountain Vipers

JEFF ETTLING
Saint Louis Zoo, One Government Drive
St. Louis, Missouri 63110-1395, USA
e-mail: ettling@stlzoo.org

Over the past decade, the Saint Louis Zoo has focused its efforts on the captive management and reproduction of mountain vipers, *Montivipera*, of the Near East. With a vested history in this snake complex, the Zoo found value in focusing its conservation efforts on a group largely ignored by other zoological institutions. The Zoo's studies of captive vipers have already provided useful information on reproduction and behavior (Ettling 1996; Ettling and Marfisi 2002).

In May 2004 the Saint Louis Zoo officially announced its new Conservation Division, the Wildcare Institute. Under the umbrella of the Institute are 12 Conservation Centers that focus on endangered species and their habitats. The goal of the Institute is to work through partnerships to help animals, ecosystems and people simultaneously. The key to the success of the Wildcare Institute will be collaboration with universities, government agencies, conservation organizations, field researchers and other zoos. The Center for Conservation of Near East Mountain Vipers will focus on helping implement conservation management and public education to ensure the future of mountain vipers in the wild.

The *Montivipera xanthina* complex is comprised of eight species with a distribution that includes southeastern Europe, Asia Minor, Armenia, and western Asia. Our limited knowledge of their natural history is due in part to restricted and isolated rocky habitats (Nilson and Andrén 1986). Over the past 20 years the combination of habitat alteration, over-collection, and unnaturally high

FIG. 1. Surgical implantation of transmitter. Individuals in photo are as follows: Alexander Malkhasyan (left), Jeff Ettling (center), Aram Agasyan (right rear), and Andy Snider (right front).

FIG. 2. Jeff Ettling demonstrating the use of radiotelemetry equipment.

mortality resulting from human persecution has drastically reduced many mountain viper populations (Nilson and Andrén 2000). In fact, five of the eight species are now listed by the IUCN as vulnerable, endangered, or critical. Unless proper equipment, public education, and human resources necessary for conducting basic conservation activities are allocated, this complex of snakes faces an uncertain future.

In June 2004 the first long-term project of the Center for Conservation of Near East Mountain Vipers was initiated. The species targeted for the inaugural study was the Armenian viper, *Montivipera raddei*. The population numbers of *M. raddei* have dropped a staggering 88% over the past 20 years, primarily because of habitat alteration and over-collection. As a result it is listed as a species of concern in Armenia's National Red Data Book. For effective conservation of *M. raddei*, as well as other species, it will be necessary to establish a network of nature reserves. With little data available on home range size and demography, it is difficult to make sound management decisions at the current time.

The project is a collaborative effort that involves individuals from five institutions: Jeff Ettling (Saint Louis Zoo), Andy Snider (Detroit Zoological Institute), Dr. Nikolai Orlov, Dr. Natalia Ananjeva, and Roman Khalikov (Russian Academy of Sciences), Dr. Aram Agasyan and Alexander Malkhasyan (Armenia Ministry of Nature Protection), and Konstantin Shiryaev (Tula Exotarium, Russia).

The study is utilizing radio-telemetry and mark/recapture to determine the home range size, seasonal activity patterns, habitat preferences, and demography of *M. raddei*. Our selected study site is in Khosrov Nature Reserve, considered one of the most important protected areas in Armenia because of its unique plant and animal communities. Over 50% of all Armenian plants and 171 animal species (60 endemic species) are represented in the Reserve. To date, six vipers have been implanted with radio transmitters. An additional four snakes were planned to be implanted with transmitters in May 2005. The movement patterns and habitat preferences of these snakes will be monitored for a period of five years. In addition to the specimens with transmitters, all *M. raddei* that are captured within the study site are sexed, weighed, measured, and permanently marked for future identification with subcutaneous implanted passive transponders.

Although the radio-telemetry study will provide the fundamental information necessary for development of conservation management guidelines for *M. raddei*, it must also be accompanied by a strong educational component. With assistance from the Zoo's education staff, a poster and brochure currently are being developed. The field team will use these materials in outreach programs in rural communities and with pastoral farmers who often encounter the snakes. Future plans include a workshop for teachers in Armenia that will provide them with curricula on ecosystems, conservation, and the plight of the Armenian viper. It will also be important to provide training for future educators. A family in St. Louis, Missouri, interested in assisting our project, has offered to sponsor an Armenian exchange student who will be pursuing a career in environmental education. A search is currently underway and a student should be in place in 2006.

Through the combination of ecological fieldwork, development of management guidelines, and an intensive outreach education program, our goal is to establish a secure future for *M. raddei* in Armenia. In addition to continuing our work in Armenia, the Center for Conservation of Near East Mountain Vipers plans to pursue other collaborative projects involving the other seven species of mountain vipers.

Questions regarding the Armenian Viper Project or Center for Conservation of Near East Mountain Vipers should be directed to Jeff Ettling (e-mail: ettling@stlzoo.org). Further information about the Wildcare Institute and/or its Conservation Centers is available from the Saint Louis Zoo's website (www.stlzoo.org).

Aspidoscelis Versus *Cnemidophorus* as a Genus of Whiptail Lizards in North America

TOD W. REEDER
Department of Biology, San Diego State University
San Diego, California 92182-4614, USA
e-mail: treeder@sunstroke.sdsu.edu

and
CHARLES J. COLE

e-mail: cole@amnh.org

A recent announcement of Publications Received [Anonymous, 2004. Herpetol. Rev. 35:205] mentioned that Axtell (2003) "... retains usage of *Cnemidophorus sensu lato*, treating *Aspidoscelis* as a subgenus (by extension, *Ameiva* and *Kentropyx* are also regarded as subgenera)..." This raised the questions of what evidence Axtell used and what generic name(s) he intended to use for the subgenera *Ameiva* and *Kentropyx*. We obtained a copy of Axtell (2003) from the author and here we review this matter further.

Axtell (2003:1) reviews aspects of the biology of "*Cnemidophorus* (*Aspidoscelis*) *exsanguis* Lowe" in Texas, with emphasis on distribution. He presents no new evidence bearing on the question of which generic name is appropriate for this taxon, or other species of North American whiptail lizards, nor does he present evidence contradictory to the conclusions of Reeder et al. (2002). Instead, he rebuffs these conclusions with the following two sentences: "In this account I have treated *Aspidoscelis* as a subgenus of *Cnemidophorus*, rather than changing that name with its over 200 year nomenclatural history. With this action, I realize that both *Ameiva* and *Kentropyx* would also be reduced to subgeneric rank, but with the molecular data indicating paraphyly among these two groups (Reeder et al. 2002), this may [be] the best option until more is known" (Axtell 2003:9). This is not only a rejection of certain well-supported conclusions of Reeder et al. (2002) in the absence of new data, but it is also a misunderstanding of their comments. In addition, Axtell does not explicitly indicate what generic name he would apply to the subgenera *Ameiva* and *Kentropyx* that he mentions. His writing implicitly suggests that these taxa would represent additional subgenera of *Cnemidophorus*. While this alternate strategy is generally consistent with the phylogeny, such a taxonomic decision would violate Article 23 (principle of priority) of the International Code of Zoological Nomenclature (1999). We write to clarify the situation and restate our conclusion that *Aspidoscelis* is the most appropriate generic name for the North American whiptail lizards.

Reeder et al. (2002) presented an extensive phylogenetic analysis of 39 taxa of teiine macroteiid lizards (representing "*Ameiva*," "*Cnemidophorus*," *Dicrodon*, *Kentropyx*, and *Teius*), using several teiid and non-teiid outgroups. Phylogenetic trees were generated on the basis of combined mitochondrial DNA sequence data, allozyme data, and morphology, then compared *a posteriori* with karyotypic data for consistency. While various parts of the phylogenies generated had differing levels of support indicating that more research is needed to resolve the relationships among teiines, one aspect of the analyses was clear: the genera *Ameiva* and *Cnemidophorus sensu lato* are paraphyletic.

The South American species in the *Cnemidophorus lemniscatus sensu stricto* species group, containing the type species of the genus, were strongly supported as a clade, with this group being more closely related to *Kentropyx* and most species of *Ameiva* than to the whiptail lizards of North America (Reeder et al. 2002). However, all of the North American species analyzed in the *deppii*, *tigris*, and *sexlineatus* species groups of *Cnemidophorus sensu lato* (and by extension the *cozumela* and *tesselata* species groups) comprised a strongly supported monophyletic group that appears to be distantly related to most of the Neotropical taxa (Reeder et al. 2002).

This left Reeder et al. (2002) with various options to consider with respect to taxonomic changes: (1) suggest no changes in taxonomy, and therefore not even recognize the strongly supported North American clade as a distinct lineage; (2) recognize as a genus the strongly supported clade, but, for stability, make no other changes until the phylogenetic history of the other groups is clarified by future research; or (3) address the widespread paraphyly by combining all species of *Ameiva*, *Cnemidophorus*, and *Kentropyx* into one genus, perhaps applying subgenera in an attempt to preserve some taxonomic stability within this complex and large clade, but in which case, the oldest name would be the generic name *Ameiva* Meyer 1795. Given the strong support for the clade of North American taxa and the remaining levels of uncertainty requiring more research, we chose the second alternative as being a conservative way to apply nomenclature. Placing all species of *Kentropyx* and *Cnemidophorus* into the genus *Ameiva* would be a provisional resolution at best and would obscure the phylogenetic history already retrieved, as would suggesting no taxonomic changes.

Reeder et al. (2002) did not enjoy changing long established names; we prefer nomenclatural stability but require that it be consistent with phylogeny. We made one change of a generic name, thereby adopting the most conservative approach that is consistent with the evidence and based on a philosophy of phylogenetic systematics. This is the same reasoning used in recognizing that snakes and lizards are members of Squamata, although many decades ago this required shifting Serpentes out of Vermes. Change often is the cost of advancing knowledge. The use of *Aspidoscelis* Fitzinger 1843 as the genus for the North American whiptails was not a matter of personal choice. Following Article 23 of the International Code of Zoological Nomenclature (1999), Reeder et al. (2002) used the oldest name available within the synonymy of *Cnemidophorus*.

We note that Axtell (2003) has apparently adopted a nomenclatural approach akin to our option 3 above. Though not explicit, it appears that Axtell (2003) is advocating recognition of several subgenera within an expanded genus *Cnemidophorus*. He explicitly places *Aspidoscelis* as a subgenus of the genus *Cnemidophorus* and implies that *Ameiva* and *Kentropyx* would also be subgenera of *Cnemidophorus*. Axtell does not mention the South American taxa of the *Cnemidophorus lemniscatus* species group (*sensu lato*),

but his recognition of *Aspidoscelis* as a subgenus implies that he would treat the taxa of the *C. lemniscatus* species group as members of a subgenus *Cnemidophorus*. If this is what Axtell is recommending, we note that this would be in violation of Article 23 of the International Code of Zoological Nomenclature (1999), as *Ameiva* would have priority over *Cnemidophorus* as the generic name.

If we have inaccurately assumed Axtell's (2003) intended new subgeneric classification mentioned above, then there are only two other options he might be advocating. The first would be for *Ameiva* and *Kentropyx* to be subgenera within either an expanded genus *Ameiva* (oldest available name) or an expanded genus *Kentropyx*. In both cases, phylogenetic principles would be violated as the species of the subgenus *Kentropyx* (whether considered to be in the genus *Ameiva* or *Kentropyx*) are more closely related to members of the genus *Cnemidophorus* (members of the *C. lemniscatus* species group *sensu stricto* of South America) than to species of *Ameiva*. Alternatively, Axtell (2003) could be recommending the recognition of *Ameiva* and *Kentropyx* as separate genera, each with a single nominate subgenus. If so, not only would this complicate the nomenclatural situation with the erection of redundant taxa (i.e., subgeneric content being equivalent to generic content), but also it would do nothing to correct the paraphyletic nature of *Cnemidophorus sensu lato*.

In Reeder et al. (2002) nomenclatural stability was best served by avoiding additional generic changes (beyond resurrecting *Aspidoscelis*) until future evidence is brought to bear on other parts of the phylogeny, by not lumping all of the taxa into *Ameiva* while awaiting that evidence, and by not erecting formal subgeneric taxa that would be temporary. Stability is not served if the results of Reeder et al. (2002) are rejected or modified without bringing new data or analyses to bear on these issues. New data, however, have been collected recently. With much more mtDNA sequence data (i.e., 2609 bp vs. 876 in Reeder et al. [2002]) and several additional Neotropical teiine taxa (including the type species of *Cnemidophorus*, *C. murinus*), new analyses and results provide additional strong support for the recognition of the North American clade of *Aspidoscelis* (Reeder, Bell, and Cole, unpubl. data). In conclusion, we encourage use of the genus *Aspidoscelis* for North American whiptail lizards as specified by Reeder et al. (2002) and, until further evidence or analyses are brought to bear on this issue, we reject Axtell's (2003) unjustified allocation of *Aspidoscelis* as a subgenus of *Cnemidophorus* sensu lato.

Egg Attendance by Female Frogs in Two Species of *Eleutherodactylus* from Costa Rica

MASON RYAN
Department of Zoology, Southern Illinois University at Carbondale
Carbondale, Illinois 62901-6501, USA
e-mail: eleuth@zoology.siu.edu

Eleutherodactylus crassidigitus and *E. fitzingeri* are common inhabitants of the forest floor of humid lowland and premontane forests from Costa Rica through Colombia, occurring from sea level to 1500 m in elevation (Savage 2002). Although relatively common, little information is available on the reproductive biology of these species. Both species, as well as most members of the genus, lay encapsulated eggs out of water and undergo direct development within the egg bypassing the larval stage and hatching out as miniature adults (Savage 1975). The secretive nature of these and many other species of *Eleutherodactylus* makes collection of detailed ecological observations haphazard and fortuitous at best.

In the only report of egg attendance in *E. crassidigitus*, Taylor (1952) reported finding an adult and 26 eggs under a rock. There are two reports of egg attendance in *E. fitzingeri*. Dunn (1931) found 44 eggs attended by an adult frog, which he identified as a male, but based on size alone, 51 mm snout to vent (SVL), Lynch and Myers (1983) suggested it was a female. Mendoza Quijano et al. (2002) reported a female *E. fitzingeri* attending 85 eggs in a small cavity on the ground. These three observations suggest that *E. crassidigitus* and *E. fitzingeri* may provide parental care to their eggs (Townsend 1996). Egg attendance occurs in at least 48 of the more than 525 species of *Eleutherodactylus* and of these, 24 species exhibit female attendance of eggs (Crump 1996, Townsend 1996). Herein I describe female clutch attendance for *E. crassidigitus* and *E. fitzingeri* with notes on egg deposition sites, clutch size and hatchlings.

I made observations along the south central Pacific coast of Costa Rica at the following localities: Hacienda Baru National Wildlife Refuge, Dominical, Puntarenas (09˚16'00"N, 83˚52'20"W, 10 m

Table 1. Summary of attending female snout–vent length (SVL) and eggs per clutch of *Eleutherodactylus crassidigitus*. Means reported as $\bar{x} \pm$ 1 SD.

Date	Female SVL (mm)	Eggs Per Clutch

13 June 2001	43	47
3 July 2001	45	45
	$\bar{x}$ = 41.4 ± 2.6	$\bar{x}$ = 39.0 ± 8.8

elev.); Finca Los Arboles, Tres Piedras, Puntarenas (09˚19'30"N, 83˚52'0"W, 95 m elev.); and Quebrada Grande, Palmar Norte (08º57'95"N, 83º26'60"W, 90 m elev.). This area is tropical moist forest and receives 2500–4000 mm of rainfall annually, and experiences a dry season from late December through April (Campbell 1999).

During a 26-month period from 19 December 1999 through 15 May 2002, I encountered 11 female *E. fitzingeri* attending clutches and five *E. crassidigitus* attending clutches during quadrat and transect sampling. I measured SVL with a 15 cm plastic ruler and egg diameter with dial vernier calipers. I found all 16 clutches under leaf litter. After I removed and counted eggs I replaced them and attending female within 5 cm of the eggs and replaced the leaf litter on top pf both. In two additional cases I obtained egg counts by dissection of gravid *E. fitzingeri*. The eggs of both species were non-pigmented, spherical with yellowish yolk, and were clustered in a grape bunch although not connected by a jelly or foam matrix.

I found 5 female *E. crassidigitus* attending clutches in the months of May (N = 2), June (N = 2), and July (N = 1). In all cases the attending frog was sitting on top of the clutch and were covered by leaf litter. One adult female and a clutch were collected and deposited in the collection of the University of Costa Rica (UCR 14759).

Oviposition sites were associated with shady microhabitats within the forest floor. I found three clutches near the buttresses of large trees: two clutches were found in vertical crevices inside the buttresses of *Brosimum utile*, and one clutch was under deep leaf litter near the root mass of a *Ceiba pentendra*. I discovered a fourth clutch in the crack of a large boulder and a fifth in the deep leaf litter of *Scheelea rostrata* fronds. I found 11 female *E. fitzingeri* attending clutches in the months of January, February, April, June, and September (Table 2). I collected one attendant female and two gravid females and deposited them at UCR (UCR 14714, 16031, 16033).

I recorded seven clutches in primary forest and four clutches along streambeds. All were under leaf litter in deep shade, and nine clutches abutted roots, logs, buttress or boulders. All nests were circular inside a depression in the soil with the eggs flush with the surface of the ground. A small, raised, ridge of soil and debris surrounded the edge of each nest. It appeared that females created or modified these basins by clearing them out of all debris. When a female was brooding, her body completely covered the entire clutch. These females became rigid and flattened when disturbed and remained in this position when handled.

From 9 to 18 February 2002 I marked and monitored one attending female twice daily, once in the morning and once at night, for 10 days. During the day the attending female was always sitting on the eggs. The female attended the clutch everyday, and 8 out of 10 nights, until she disappeared. The eggs were not ready to hatch, and I estimated them to be at approximately stage 9 of development based on tail movements (Townsend and Stewart 1985).

Females attended eggs until they hatched. On three occasions I found females attending nests in the process of hatching. Hatchlings were found hopping on and under the leaf litter. The nests contained the remnant egg capsules. From 1 to 4 June 2001 I monitored a nest of new hatchlings dispersing from the nest. A female frog remained next to the clutch for three days until all hatchlings had dispersed. I observed a similar behavior on two other occasions. Hatchlings of *E. fitzingeri* had a visible yellow yolk sac and a mean SVL of 7.2 ± 0.74 mm (N = 36).

The average clutch size of *E. fitzingeri* was 62.1 ± 18.7 eggs with a range of 24 to 81 (N = 8, Table 2). A positive correlation exists between clutch size and female SVL ($r^2 = 0.54$, df = 7, N = 8) as has been reported in other *Eleutherodactylus* species (Wake 1978). I dissected two gravid females and counted 84 and 92 eggs, respectively. I excluded these from the analysis because it is unknown whether this species deposits multiple clutches. Egg diameter ranged from 2.80 mm to 5.71 mm for 99 eggs measured of four clutches (Table 2).

TABLE 2. Summary of clutch characteristics of *Eleutherodactylus fitzingeri*. Means reported as $\bar{x}$ ± 1 STD; all measurements are in millimeters.

Eggs attendance is the most common form of anuran parental care (Wells 1981) and can serve many functions including: protection against predators and pathogens, aeration of aquatic eggs, hydration of terrestrial eggs, prevention of developmental abnormalities, and to assists hatchlings as they emerge from the nest (Crump 1994). In the case of terrestrial breeding species the principle function of parental care includes hydration of eggs and protection from invertebrate predators (Townsend 1996), which may be the case in *E. crassidigitus* and *E. fitzingeri*. This paper confirms the anecdotal observations of Dunn (1931), Mendoza Quijano et al. (2002), and Taylor (1952), that females of these two species provide parental care to their clutches by egg attendance. 100% of the clutches I found had an attending female present indicating that clutch attendance is obligatory and not facultative.

Acknowledgments.—This study was supported by Hacienda Baru National Wildlife Refuge, Dominical Costa Rica and Tropical Forestry Initiative through U.S. Forest Service Grant #03-DG-11132762-964. I would like to thank K. R. Lips, K. Regester, C. Leopold, and A. J. Crawford for their helpful comments in reviewing this manuscript. F. Bolaños and G. Chavez for assistance and encouragement in conducting field work in Costa Rica. Finally, Y. Maurer and D. Merritt assisted me in the field often under tedious and uncomfortable conditions.

Defensive tail displays are often exhibited by snakes with bright and/or blunt tails in response to a stressor or a tactile stimulus and depending on the species, these displays can vary in speed, duration, frequency and proportion of tail length used (Greene 1973). Tail displays also make the tail visually obvious to a potential predator and may provide survival value to a snake by intimidating the predator, diverting the predator's attack away from the head and toward the tail, or distracting the predator and thus allowing the snake to strike or escape (Greene 1973). While rattling in rattlesnakes is a well-known defensive tail display used in potentially dangerous situations, non-rattling defensive tail displays might also function either as warning, distraction, or disorientation mechanism as they do in non-rattlesnakes (Greene 1973, 1988, 1992, 1997; Klauber 1972). As part of a larger repertoire of defensive behaviors, non-rattling tail displays might be particularly useful for rattlesnakes with inaudible or barely audible rattle chains or for those rattlesnakes possessing an insufficient number of rattle segments to produce a rattling sound. Here, we document a non-rattling defensive tail display for the first time in the Dusky Pygmy Rattlesnake, *Sistrurus miliarius barbouri*.

Sistrurus miliarius barbouri is a small rattlesnake species, seldom exceeding 55 cm, that has a bright yellow tail as a juvenile and a disproportionately small rattle compared to other rattlesnake species. Rowe et al. (2002) reported high rates of rattle loss in this species, with approximately one-half of all snakes examined possessing fewer than two interlocking segments. Because at least two interlocking segments are needed to produce a rattling sound, approximately one-half of all Pygmy Rattlesnakes are incapable of producing a rattling sound (Rowe et al. 2002). In field observations associated with another study, we noticed that in addition to rattling, this snake undulates its tail when captured. The entire tail is swayed back and forth in large arcs, while the distal half of the tail is wiggled in smaller sinusoidal movements. Both motions occur at a faster speed than those observed when this species caudal lures, and are often interrupted by brief periods of rattling that last approximately one second. Based on these observations and the bright and often rattleless tail of *S. m. barbouri*, we hypothesized that these undulatory (not vibratory) tail movements are a defensive tail display that is part of the typical defensive repertoire in *S. miliarius*. Based on this hypothesis and Greene's (1973) observations, we made two predictions about what we might ex-

pect to see in more detailed field observations of this species. First, if this tail display is a defensive behavior, then it should be used in response to tactile stimuli from a potential predator, as in other species observed by Greene (1973). Second, if tail movements function as a mechanism that compensates for missing rattle segments, then we predicted that *S. miliarius* with fewer than two rattle segments (and thus inaudible rattles) would display tail movements more often than do snakes with longer rattle chains.

TABLE 1. Comparison-wise summary of median time (minutes ± 1 standard deviation) and mean time (minutes ± 1 standard error) spent by *Sistrurus miliarius barbouri* displaying tail movements. Observations were made for up to two minutes following capture.

Comparison	N	Median ± 1 SD	Mean ± 1 SE
Snakes with < 2 rattle segments	11	0.5 ± 1.01	0.95 ± 0.30
Snakes with > 2 rattle segments	28	0.23 ± 0.92	0.81 ± 0.17
Adults	23	1.5 ± 0.96	1.10 ± 0.2
Juveniles	16	0.00 ± 0.80	0.47 ± 0.20
Females	22	0.71 ± 0.96	0.95 ± 0.21
Males	17	0.00 ± 0.92	0.72 ± 0.22

Materials and Methods.—To test our hypothesis, we made observations on snakes from Rock Springs Run State Reserve in Lake County, Florida (USA), between June and November of both 2001 and 2002. We located adult (≥ 2 yrs) and juvenile (1–2 yrs) snakes by visual survey and noted if the snake rattled or undulated its tail upon approach and for up to two minutes following capture by gloved hands. We also recorded the duration of tail undulations. We determined age using measures of snout–vent length, tail length, and mass reported for this species by Bishop et al. (1996). We used a two-tailed Fisher's exact test and a Mann-Whitney *U* test to analyze frequency and duration data, respectively.

Results and Discussion.—We never observed a non-rattling tail display before capture in our study population. Non-rattling tail movements were exhibited only after capture and moreover, they were used in equal frequency to rattling (χ^2 = 0.21, df = 1, P = 0.65, N = 39). The frequency and duration of tail movements were not significantly correlated with number of rattle segments (χ^2 = 0.003, df = 1, P = 0.96; U = 19.6, P = 0.74), age (χ^2 = 2.92, df = 1, P = 0.09; U = 16.1, P = 0.08) or sex (χ^2 = 0.56, df = 1, P = 0.45; U = 15.5, P = 0.47). Median and mean durations of tail display are reported in Table 1.

Crypsis is often the first line of defense for rattlesnakes, with other behaviors exhibited as graded responses to escalating threat (Duvall et al. 1985). Non-rattling defensive tail display occurred in equal frequency to and concomitantly with rattling in this species. This indicates that tail display is part of a larger defensive repertoire typical of this species and because this behavior was only exhibited after tactile stimulation, is probably only used at higher levels of threat and defensive escalation. Greene (1973) suggested that tail displays may provide survival value to the snake by distracting the predator and allowing the snake to strike. In this study, pygmy rattlesnakes often struck while displaying and this observation further supports the hypothesis that this behavior is defensive in nature.

We predicted that *S. miliarius* with fewer than two rattle segments would display tail movements more often than do snakes with longer rattle chains. However, our data did not support this prediction and suggests that tail display might not be used to compensate for inaudible rattles in this species. However, even when adjusted for their small body size, the rattling of *S. miliarius* with two or more rattle segments is much quieter and higher pitched than in other pitvipers (Cook et al. 1994). If the rattle is an ineffective warning device, regardless of chain length, then all Pygmy Rattlesnakes might be expected to exhibit non-rattling tail displays, as was observed in this study. Alternatively, this defensive tail display might reflect an ancestral trait that also occurs in other vipers, or it simply might be a behavioral atavism. Comprehensive and detailed tests covering a range of controlled stimuli and several lineages of snakes are needed to resolve these possibilities. Klauber (1972) suggested that adults often exhibit defensive behaviors more frequently than juveniles and although not statistically significant in this study, there was a trend for adults to exhibit defensive tail displays more often and for longer durations than juveniles. Although the origin and exact role of this tail display remain unclear, its use by *S. m. barbouri* in a defensive context is supported by our observations.

Defensive tail displays were observed in both adult and juvenile snakes but only juveniles exhibit a bright yellow tail color. This suggests that the bright tail color of juvenile *S. m. barbouri* may not contribute to the effectiveness of tail movements as a distraction or disorientation mechanism. Alternatively, this bright color probably enhances the optical attractiveness of the tail when used as a caudal lure (Neill 1960). Caudal luring differs from this defensive tail display in that luring is exhibited exclusively in the presence of prey, is slower in speed of undulations, uses less length of the tail and is affected by age and sex (Rabatsky 2002; Rabatsky and Waterman 2005).

Eryx johnii and *Tropidophis pardalis* are the only two other species thought to use the tail both as a defensive tail display and caudal lure (Greene 1973). Based on our observations of *S. miliarius* in the wild, this snake may be a third species that uses the tail for both behaviors. Although the specific benefits of this defensive tail display are still unclear, having a behavioral repertoire that includes multiple defense mechanisms might enable *S. miliarius* to respond more effectively to a wider variety of potentially dangerous situations, especially considering that the rattle of this species is incapable of sound production or just barely audible in most individuals.

Acknowledgments.—We thank Jack Stout, John Weishampel, Jim Roth, Buck Snelson, and Boyd Blihovde for assistance throughout various phases. Brad Moon and Bob Jaeger provided comments on the manuscript. The Florida Fish and Wildlife Conservation Commission and the Florida Department of Environmental Protection provided permits and land access, respectively. This research was supported by a UCF departmental grant to AMR and was completed in partial fulfillment of the requirements for the M.S. degree. This study was approved by the Univer-

sity of Central Florida Animal Use and Care Committee (Protocol #0105) and all methods adhered to the guidelines set forth by the Institutional Animal Care and Use Committee for Wildlife Field Studies.

Eleutherodactylus johnstonei Barbour 1914 is an endemic species of many islands of the Lesser Antilles (Frost 1985). It is widely distributed in the Eastern Caribbean (Kaiser and Hardy 1994) and in northern South America (Frost 1985; Kaiser et al. 2002; Ovaska 1991) where it is associated with urban areas. It has been introduced by natural phenomena and by human activity (Kaiser et al. 2002). In Colombia it has been reported in the cities of Barranquilla (Acosta - Galvis 2000; Ruiz-C. et al. 1996), Cali (F. Castro in Kaiser et al. 2002), and Bucaramanga (Ortega et al. 2002).

Diet and microhabitat use of *E. johnstonei* have been studied only in a population of Barbados (Ovaska 1991), where the species is probably indigenous (Marsh 1983). For this population the most abundant prey found was Formicidae, followed by collembolans, dipterans, and homopterans, among others. The individuals of this population use bromeliads, trunks, leaf litter, and small rocks as diurnal refuges, and during the night they are active across the arboreal stratum. In recently colonized areas, these ecological data have not been recorded although such information could contribute to an understanding of why this species is a successful invader. Here, we report on diet composition and microhabitat use in an introduced population of *Eleutherodactylus johnstonei* and compare these data with those from native populations.

Materials and Methods.—The studied population is located in the house gardens of Bucaramanga (Santander, Colombia; 07˚07' 28.7"N and 73˚06'41.6"W, 1040 m altitude). The area has a nearly constant bimodal regime of rains and a mean temperature of 24˚C during the year. The vegetation in the gardens is characterized by a variety of ornamental plants. Individual frogs were collected in gardens in leaf litter and on bushes between 2000 and 2200 h. Additional searches were made in forests bordering the study site, to determine presence adjacent to gardens and whether there has been displacement of native frogs by the introduction of *E. johnstonei*. Initially, we collected 30 frogs and made an analysis of minimum sample size using a saturation curve of consumed prey. We monthly collect 17–20 individuals (May of 2001 through

April of 2002) following the suggestions of this previous analysis. We collected frogs larger than 15 mm snout–vent length (SVL) to facilitate handling in the laboratory. Following the suggestions of Heyer et al. (1994), we recorded SVL, mouth width (MW), substrate type (soil, leaf litter, leaves, trunks, rocks, and grass) and perch height. Individuals were euthanized and fixed in 10% formalin to interrupt the digestive processes and prey decomposition. Specimens were deposited in the Herpetological Collection of the Museo de Historia Natural, Universidad Industrial de Santander (UIS-A).

Leaf litter arthropods were collected with an insect net and Berlesse funnel at the study location. They were preserved in 70% ethanol and were used as reference samples for comparisons and determination of the stomach contents of the collected frogs. Digestive tracts of each individual were removed and their contents preserved in 70% ethanol. Taxonomic determinations of prey were made using the keys of Borror et al. (1989). Fragments that showed identification problems were compared with preserved samples of arthropods. Number and percentage of prey per stomach was recorded. An index of relative importance was calculated to evaluate the contribution of each category to this population's diet (following Pinkas et al. 1971). We tested correlations between frog SVL and MW and the size and volume (using the ovoid spheroid formula, Caldwell and Vitt 1999) of the ingested prey to see if prey size depends on frog corporal size or mouth size. Chi-square tests were used to investigate whether significant statistical differences existed in the use of the microhabitat and perch height.

Results and Discussion.—We dissected 212 stomachs (140 males and 72 females), revealing 1448 prey items identified to order, and grouped into 22 categories excepting members of Formicidae. Diet was composed of insects and other arthropods such as spiders and isopods (Crustacea), and other prey as gastropods and oligochaetes (Table 1). Although there was some plant material in the diet, these were not included because only two of the 212 dissected stomachs contained these items.

Traditionally it has been thought that anurans have a generalist diet, which reflects the richness and size of the resource (Duellman and Trueb 1986). Our results suggest that *E. johnstonei* is a carnivorous generalist species as determined by the presence of a variety of prey items such as homopterans, orthopterans, thysanopterans, dermapterans, gastropods, formicids, collembolans, and isopods. A generalist diet is likely one of the characteristics (but not the only one) that makes this frog an excellent colonizer.

TABLE 1. Diet composition of males and females of an introduced population of *Eleutherodactylus johnstonei*. Numerical importance (number of prey item in relation to total number of items found in the species), frequency (percentage of prey item number in relation to total number of items found in the species), prey volume (total volume of prey category in all individuals examined), and percentage of relative importance [IRI = % FO (%V + %N), FO, percentage of stomachs containing an specific item, V volumetric importance, and N, numerical importance].

	Numerical Importance		Frequency		Prey volume		% IRI

The 22 taxonomic prey categories contribute to the individual's development according to the index of relative importance (IRI). The most important category was Formicidae (54.24%) followed by dipterans (47.16%) and collembolans (19.33%), whereas the categories with a low IRI possibly reflect opportunistic ingestions related to the abundance of these resources in the study place. In other *E. johnstonei* populations, ants were the most important prey (51.4% in Barbados; Ovaska 1991), and in Jamaica, Stewart (1979) reported two introduced species (*E. johnstonei* and *E. planirostris*) and two native species (*E. gossei* and *E. cundalli*) whose main food source was Formicidae. Also, in *E. coqui*, Lavigne and Drewry (1971) found that ants were the most consumed prey, and Duellman (1978) found that for 9 of 15 species of *Eleutherodactylus*, ants were the most consumed prey. The high percentage of ants in the diet might suggest a high availability of this resource in the sampling places not measured by any of these investigators (nor us), or that these species specialize upon ants.

However, other species of *Eleutherodactylus* are not consumers of ants. Arroyo (2002) reported collembolans and coleopterans as the most important prey for an *Eleutherodactylus* assemblage in a cloud forest of the Cordillera Oriental of the Colombian Andes. Gutierrez (2003) reported, for another assemblage of cloud forest *Eleutherodactylus*, that the most common prey items were isopods and coleopterans, in an area south of the location studied by Arroyo (2002). Ants were items that frogs consumed only occasionally in both studies; in fact, ants are typically rare at higher elevations including cloud forests. Thus, prey availability might explain the differences in diet among *Eleutherodactylus* species. Duellman and Trueb (1986) suggest external factors (seasonal abundance of the food and competitors' presence or absence) and intrinsic factors (ecological and morphological tolerances) relating to body size with the election and type of prey consumed, and with use of microhabitats for foraging.

Prey composition of each sex was not significantly different ($Z_{(139,71)}$ = -0.776212; P = 0.4376). There was also no significant differences among sexes in the numeric importance ($U_{(1,21)}$ = 209.500; P = 0.445), frequency in the stomachs ($U_{(1,21)}$ = 221; P = 0.622), volume of the ingested prey ($U_{(1,21)}$ = 236; P = 0.88) and the relative importance index ($U_{(1,21)}$ = 226.5; P = 0.91, Table 1).

The adult population of *E. johnstonei* showed a positive relationship between SVL and MW and the size and volume of the consumed prey. There was a significant correlation between SVL and prey size (r = 0.1983; P = 0.0036; N = 212) and prey volume (r = 0.148; P = 0.0308; N = 212). Similarly, there was a significant correlation between MW and prey size (r = 0.1689; P = 0.0135; N = 212) and MW and prey volume (r = 0.1974; P = 0.0038; N = 212) indicating that larger frogs and bigger mouths ingest larger prey. These relationships were also reported in a native population of *E. johnstonei* in Barbados (Ovaska 1991), in *E. coqui* (Woolbright and Stewart 1987), in six sympatric species of anurans the central Amazonian (Lima 1998), and in a subtropical community of anurans (Basso 1990) showing that changes in size and prey types with the sizes of frogs are expected by morphological reasons and for changes in the spectrum of types of prey that can be ingested (Lima and Magnusson 2000). The positive relationship between MW and the size and volume of the prey constitutes an important element supporting the ideas Toft (1980, 1981) that the width of the mouth limits the size of the prey captured by certain species.

Eleutherodactylus johnstonei used vegetation associated with the herbaceous substrate (families Araceae, Bromeliaceae, Conmelinaceae, and Poaceae) as places for calling and perching. Trees taller than 2 m (families Combretaceae and Rutaceae) provided protection against solar radiation/drying and maintained soil moisture. The analysis of substrate use allowed us to establish significant differences for this resource (soil, leaf litter, leaves, trunks, rocks, and grass) intersexually ($\chi^2_{(0,05;5)}$ = 13.11; P > 0.01) and intrasexually (males, $\chi^2_{(0,05;5)}$ = 48.3; P < 0.001 and females $\chi^2_{(0,05;5)}$ = 32.86; P < 0.001, Fig. 1).

Perch height used is also different between the sexes ($\chi^2_{(0,05;6)}$ = 16.79; P < 0.01); males perch higher than females to call, and females prefer lower perches. Among males there were no significant differences in perch height ($\chi^2_{(0,05;6)}$ = 9.3; P > 0.10), contrary to from females who showed significantly different perch heights ($\chi^2_{(0,05;5)}$ = 32.74; P < 0.001) (Fig. 2).

Most of the males were collected calling on the bush substrate whereas females were collected close to the calling sites at lower perch heights. These intersexual differences are presumed to be related with reproductive behaviors: males use higher perches to call before amplexus, but when oviposition occurs they descend to the ground because males care for the eggs, changing their use of the vertical position. Females are more associated with the soil and leaf litter, presumably in relationship with their reproductive behavior and maybe to avoid capture by predators or disturbance. Similar results were obtained in *E. fitzingeri* (Höbel 1999) and in anurans of Anchicayá where the males are arboreal and the females are associated with the soil and leaf litter (Vargas and Castro 1999). Thus, the substrate and perch height used for by frogs may be more closely related to reproduction than with food availability, although these two activities are not completely separated.

At Bucaramanga, *E. johnstonei* is limited exclusively to the vegetation of the gardens. In the forest patches near to the gardens, we did not find *E. johnstonei* nor did we hear their song. In this

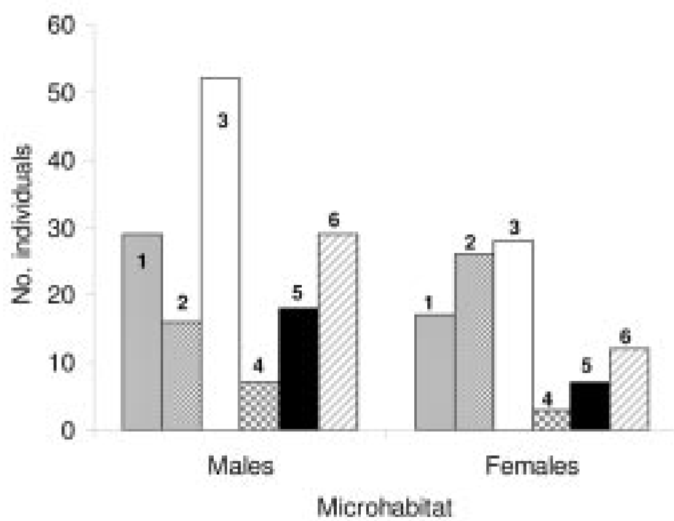

FIG. 1. Substrate used by *Eleutherodactylus johnstonei* (inter and intrasexes). 1) soil, 2) leaf litter, 3) leaves, 4) trunks, 5) rocks, 6) grass. Analysis of substrate use showed that there were significant differences for this resource intersexually and intrasexually.

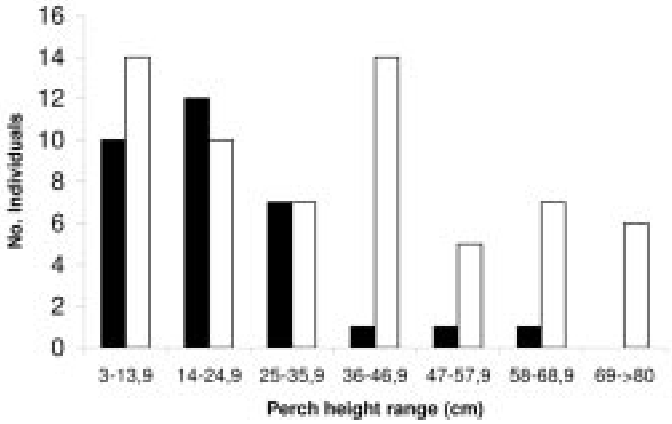

FIG. 2. Perch height used by both sexes of *Eleutherodactylus johnstonei*. Males, white blocks; females, black blocks. Intersexual differences in perch height ranges are presumed to be associated with reproductive behaviors: most males were found calling on leaves of bushes whereas egg-guarding males and females were found at lower perches in different substrates.

zone, we found native species (*E. raniformis* and *E. taeniatus*), which are absent from the gardens of the city. The adjacent vegetation of the neighborhood where the population of *E. johnstonei* is found corresponds to a highly disturbed tropical dry forest on the Andean slopes to the east of the city. Possibly this forest does not have the humidity and microhabitat features required for the survival of the species, similar to those permanently irrigated gardens, which can provide an ideal habitat for reproduction and other physiological aspects. Because native species are absent in the residential areas, *E. johnstonei* enjoys great success in these empty niches. Thus, at present, we have not been able to observe displacement of native species by the arrival of *E. johnstonei*. Although *E. johnstonei* is a generalist species in diet and microhabitat use allowing it to easily colonize new territories, these characteristics do not explain why this species is associated almost exclusively with houses gardens and not other neighboring disturbed areas at this locality.

Acknowledgments.—We thank the Laboratorio de Biología Reproductiva de Vertebrados of the Universidad Industrial de Santander for economical support to this project, the use chemicals and laboratory equipment, the Corporación Regional para la Defensa de la Meseta de Bucaramanga (CDMB) for the collection permits, and L. Navarro, G. Castillo and M. Baron, students of the Escuela de Biología, UIS, for help in the capture of the frogs. We also thank John D. Lynch for his important comments on the manuscript and for his help reviewing the English.

Frogs of the genus *Eleutherodactylus* are the main component of many neotropical herpetofaunas (Scott 1976). However, very little is known about their natural history, and even less information is available on the form and function of their vocalizations. For most species only short call descriptions are published, and for others it is unknown whether they vocalize at all. Yet, the few members of the genus *Eleutherodactylus* whose vocal behavior has been studied in detail show a great diversity of vocalizations: specialized calls for courtship and mating have been reported (Ovaska and Caldbeck 1997), as well as calls for the defense of retreat sites (Stewart and Rand 1991) and even calls produced by females in response to male calls (Schlaepfer and Figeroa-Sandi 1998).

I studied the vocal behavior of *Eleutherodactylus fitzingeri*, a common inhabitant of the tropical lowland forests of Costa Rica (Savage 2002). Although the distribution of *E. fitzingeri* extends from Nicaragua to central Colombia (Lynch and Myers 1983), to date all available information on the vocalizations of this species comes from frogs recorded in Panama (Fouquette 1960; Ibáñez et al. 1999; Lynch and Myers 1983). I provide data on geographic variation of the advertisement calls within Costa Rica and suggest that a vocalization formerly named the "sporadic call" (Ibáñez et al. 1999) is in fact a highly variable aggressive signal.

Material and Methods.—My main study site was at La Selva Field Station, Heredia Province, in the Caribbean lowlands of Costa Rica. I also recorded some frogs from the Pacific lowlands at Marenco Lodge, Puntarenas Province. I used a Sony WM-D6C tape recorder and a Sony ECM 969 microphone to record the calls of males (at ambient temperature of 25–28˚C). I either recorded completely undisturbed calling males or I vocally imitated their advertisement call and recorded their vocal response. Whenever possible, I measured the size of the frogs I had recorded (snout–vent length to the nearest 0.1 mm with calipers and weighted them to the nearest mg with a Pesola scale). I digitized the recordings at a sampling rate of 22kHz and analyzed them using the program CoolEdit96 (Syntrillium Co.) on a portable computer. To test whether call variation between populations was statistically significant I calculated Mann-Whitney's U-tests.

Results.—I recorded two types of calls: an advertisement call that was produced by solitary calling males, and a distinctly different call which was given during antagonistic interactions between males or in response to vocal call imitations.

The advertisement calls (Fig. 1) recorded from Costa Rican frogs were highly variable, and consecutive calls were given in irregular intervals of several minutes. There was significant geographic variation in several call parameters. Calls from the Pacific population (N = 6) contained between 7–11 notes and had a mean ± SD duration of 1228 ± 301 ms (range: 830–1610 ms). Calls in the Caribbean population (N = 16) however contained 12–24 notes and had a mean duration of 2884 ± 597 ms (range: 1700–3900 ms). Both call duration and number of notes per call were significantly different between populations ($P < 0.001$ in both cases). Since the duration of the individual call notes was similar in both sites (mean = 10 ± 2 ms; $P = 0.88$), the difference in call duration results from Caribbean males having more notes per call and having a longer internote interval between consecutive notes (mean = 165 ± 13 ms compared to 138 ± 17 ms; $P < 0.001$). The dominant frequency of the calls of Caribbean frogs was 1931 ± 221 Hz, that of Pacific frogs was 1788 ± 27 Hz. This difference was not statistically significant ($P = 0.27$). Males from the Pacific slope were significantly larger (33 ± 1 mm) and heavier (2.6 ± 0.3 g) than males from the Caribbean site (28 ± 1mm, 1.7 ± 0.3 g; $P < 0.005$ in both cases).

To loud natural or imitated *E. fitzingeri* advertisement calls males responded with a vocalization that sounded like a series of creaking chirps (Fig. 2). Because I did not make recordings of these vocalizations at Marenco, all data given below refer to Caribbean frogs (N = 16). These response calls were produced within 6.3 ± 3.6 seconds after the offset of the rival/imitated call. On average 5.3 ± 3.0 of these calls were produced sequentially (max: 12 calls), with periods of 3.9 ± 3.8 sec of silence between consecutive calls. The mean duration of a complete sequence of response calls thus lasted 17 ± 10 sec. Individual calls contained between 1–4 notes, each of which could last from 3 to 110 ms. The duration of the individual calls was therefore highly variable (31–375 ms). Their build-up, however, followed a common scheme of increasing duration and complexity (Fig. 2). The first call was generally the shortest and consisted of one prolonged note. The following calls often increased in duration and number of notes, and generally here too an increase of note duration from start to end of the call could be observed. The dominant frequency of these calls was

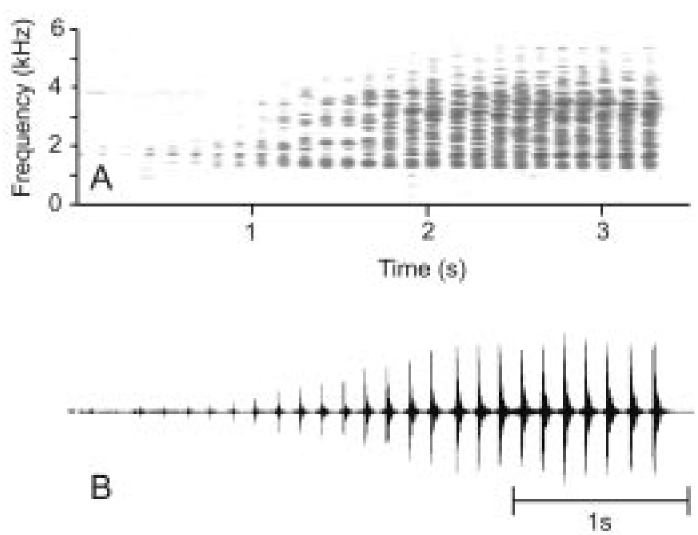

FIG. 1: An advertisement call of *Eleutherodactylus fitzingeri* recorded in Costa Rica. The upper panel (A) shows a sonagram, the lower panel (B) the waveform of the call.

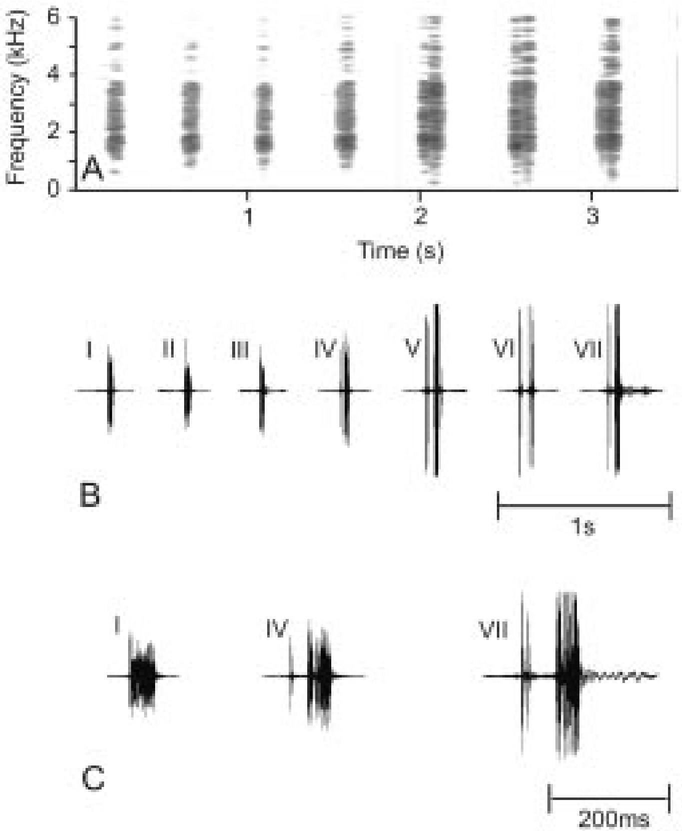

FIG. 2. Aggressive call response of *Eleutherodactylus fitzingeri* consisting of seven consecutive calls. The whole series was 29 sec long, but silent periods between successive calls were deleted in order to show the calls at the same time scale as the advertisement call from Fig. 1. Shown is a sonagram (A) and a waveform (B) of all seven calls. In (C) the waveform of the first, forth, and last call of the series are shown at expanded time scale. Note how the duration and complexity of the calls increases.

2079 ± 363 Hz. Some males showed positive phonotaxis, turning to face the source of the imitation call before responding, and certain males even moved towards the source of the call, repeatedly emitting this vocalization. Although these calls could be elicited from the majority of males by means of loud call imitations, they were very infrequently heard in nature.

Discussion.—The short advertisement calls are the most frequently heard vocalizations of *E. fitzingeri*, but because of the often large time lapses between consecutive calls, the frogs are very difficult to locate (Fouquette 1960; Lynch and Myers 1983). This may be interpreted as an avoidance mechanism against audio-orientated predators (Tuttle and Ryan 1981), and ties in with the overall life-history pattern of cryptic coloration (Lynch and Myers 1983) and secretive perch choice (Höbel 1999).

Body size might affect spectral call parameters like dominant frequency, and temperature may affect temporal call parameters like note duration, etc. (Gerhardt and Huber 2002). This should ideally be taken into account when comparing populations and describing geographic variation in call parameters. Unfortunately, my data set was not complete enough to run correlation analyses that would have eliminated these confounding factors. However, the most striking distinction between the advertisement calls of the two populations was the difference in the duration of the call, which was mainly caused by the different number of notes produced per call. Addition of call notes is to my knowledge not affected by temperature. Also, temperature should affect temporal call parameters in similar ways, e.g., lower temperatures should slow down note duration as well as the duration of the inter-note interval. In my analysis however, I found significant differences between populations in one call parameter (inter-note interval), but not the other (note duration).

Although there is geographic variation in the advertisement calls of *E. fitzingeri*, this variation does not follow a clinal pattern. Calls of Panamanian *E. fitzingeri* comprise 2–18 notes per call (Fouquette 1960; Ibáñez et al. 1999; Lynch and Myers 1983), and are thus intermediate to those of the two sites I investigated in Costa Rica. Also, the general structure of the calls is very similar between different Costa Rican and Panamanian populations (Fouquette 1960; Ibáñez et al. 1999; Lynch and Myers 1983). What is the function of this vocalization? As in most frogs, the advertisement call probably serves a dual purpose of mate attraction and territorial function (Wells 1977). Although direct evidence in form of observations of females performing phonotaxis towards a calling male or a speaker broadcasting an advertisement call is still missing, a role in pair formation is nevertheless suggested by the observation that it is the most frequently given vocalization and that it is more often given in the rainy season, e.g., during the period when reproduction takes place (Höbel 1999; Ibáñez et al. 1999). A territorial function, probably regulating inter-male spacing is suggested by males showing phonotaxis while emitting a special aggressive call (see below) when they perceive very loud advertisement calls.

Calls similar to the response calls reported here have been described for Panamanian *E. fitzingeri*. Ibáñez et al. (1999) reported hearing single one-note calls of this type, and termed this vocalization the "sporadic call." However, they did not comment on its function. Lynch and Myers (1983) elicited a similar vocalization (series of four chirps) by playing back an advertisement call that they had just recorded from the same male, which led them to suggest that this vocalization might constitute a response to conspecific male intruders. The circumstances under which this call type is given, i.e., when hearing a loud advertisement call of a rival male, together with the observation of males moving towards the source of a rival call while giving this vocalization supports the idea that it may be an aggressive call.

As a rule, the structure of a species' aggressive call differs markedly from the structure of its advertisement call (Schwartz 2001). In *E. fitzingeri* the number of notes in the aggressive call is greatly reduced compared to the advertisement call, but the duration of the aggressive call notes is increased compared to advertisement call notes. This change in call structure is different from the one found in *Eleutherodactylus* species from the West Indies, where the combination and addition of the two basic notes of the advertisement call form calls used in aggressive signaling. *Eleutherodactylus coqui* converts its advertisement call into an aggressive signal by adding advertisement call like notes to the end of it (Stewart and Rand 1991), and the aggressive signal of *E. antillensis* is comprised of a rapid series of notes that resemble the second note of their advertisement call (Ovaska and Caldbeck 1997). Based on these observations there does not seem to be a general pattern in which aggressive calls differ from advertise-

ment calls in *Eleutherodactylus*, but comparative data on aggressive calls in this frog genus is too scarce to draw any conclusions yet.

Eleutherodactylus coqui has highly variable aggressive calls, and a graded increase in aggressive call duration is related to retreat site defense (Stewart and Rand 1991). In *E. fitzingeri* the variability in duration and structure of the aggressive call suggests that males may be able to respond in a graded fashion to increasing levels of intrusion/competition as well. However, playback experiments with advertisement calls varying in intensity and thus implying varying distance to rival males are needed to elucidate whether *E. fitzingeri* does in fact have a graded aggressive communication system.

For *E. fitzingeri* from Panama a third vocalization has been described. Ibáñez et al. (1999) mention that females occasionally gave repeated screams when seized, suggesting a distress vocalization. I never heard a distress call while catching frogs in Costa Rica (both males and females), but I also did not make an effort to elicit or record distress calls.

Acknowledgments.—I thank the German Academic Exchange Service for financial support and F. Bolaños and R. L. Rodríguez S. for help with transportation and logistics.

Seasonal Timing of Follicular Development of the Mud Snake, *Farancia abacura* (Colubridae)

WILLIAM I. LUTTERSCHMIDT*
SARA B. TURK**
and
EVERETT D. WILSON
Department of Biological Sciences, Sam Houston State University, Huntsville, Texas 77341-2116, USA

**Corresponding author; e-mail: lutterschmidt@shsu.edu*

There is limited information on the seasonality of reproduction of mud snakes, *Farancia abacura*. Observations of reproductive behavior in this species are difficult both in captivity and the wild due to its secretive habits. There are several reports of oviposition and subsequent hatching (Goldstein 1941; Meade 1935b, 1937, 1940a,b, 1945; Reynolds and Solberg 1942), but little is known about seasonally dependent follicle size.

Although complete records of breeding and reproductive habits are limited, Meade (1946) discussed the natural history of *F. abacura*, including reproductive behavior, oviposition, and maternal care. He maintained a live collection of *F. abacura* and produced the first record of breeding habits in *F. abacura* (Meade 1946). Mating and oviposition occurred in July and September, respectively, with the eggs incubating for seven weeks prior to hatching. Hatching of seven clutches occurred between September and October, with incubation periods ranging from seven to nine weeks (Meade 1946). More recently, Robinette and Trauth (1992) investigated both female and male reproductive cycles from mud snakes collected throughout Arkansas. The greatest mean follicle diameter was observed in May and June, synchronal with testicular recrudescence in males.

We examined 129 female *F. abacura* from throughout their range to investigate the seasonal timing of follicular development and discuss the possible relationship between seasonal emergence and the seasonal timing of reproduction.

Materials and Methods

Data Collection from Museum Specimens.—Data were collected on oviductal follicle size, snout–vent length (SVL), head width (HW), head length (HL), and total length (TL) of *F. abacura* from adult female museum specimens (Appendix I). Ovarian follicles and oviductal tissue samples were removed through a ventral incision and stored in 70% ethanol for later measurement. Follicles were measured with a Fowler dial caliper and classified based on length according to Betz's (1963) system [Class I = 0.1–5.0 mm; Class II = 5.1–10.0 mm; Class III = 10.1–20.0 mm; and Class IV = 20.1–46.0 mm]. This system allowed for each follicle to be grouped into one of four distinct size classes and is commonly used in studies investigating follicle size and development (e.g., Goldberg 2002; Holycross and Goldberg 2001; Kofron 1979b, 1983; Rosen and Goldberg 2002).

Descriptive Analyses.—We present descriptive data on season-

ally dependent follicle length from 76 of 129 females examined. The number of female specimens collected each month was compared to the number of males and juveniles collected per month, demonstrating the possible influence of follicular development on the differences in seasonal emergence and activity between these demographic groups. Follicle size also was compared among months and regressed against female body size to determine if body size correlates with follicle size.

Results

We examined 129 females for data on morphology and follicle length. Only 76 specimens provided reproductive data that could be used in our analyses, due to damaged follicles (e.g., road killed specimens) or previous dissection. Specimens were sampled primarily from Louisiana and Texas, with some adults from Florida, Mississippi, Oklahoma, South Carolina, and Tennessee (Table 1).

Most museum specimens sampled were collected between March and June, with the greatest number of females collected in April (Fig. 1). All museum specimens collected from September to December were from Louisiana and Texas populations. Museum records indicate that females tended to be captured more often than males and juveniles throughout the year.

Mean follicle lengths for *F. abacura* were compared within their respective months of capture (Fig. 2). Class II follicles were prevalent throughout the year. However, mean follicle length is greatest in June and July, as more Class III follicles were found for these months. Of the 76 females examined, only one follicle (35.3 mm) in one female (SVL = 92.3 cm, TCWC 45620) form Brazos Co., Texas was observed in the developmental stage of Class IV. However, this female's mean follicle length was still within the Class III developmental stage.

Snout–vent length (SVL) in adult female *F. abacura* ranged from 53.4–191.0 cm (mean ± SE = 93.14 ± 2.556, N = 110); 47.0–122.0 cm in adult males (mean ± SE = 71.60 ± 1.769, N = 62) and 14.5–45.0 cm in juveniles (mean ± SE = 27.50 ± 1.346, N = 50). We found no relationship between female body size (SVL) and mean follicle length in *F. abacura*, as SVL explained only 2% (r^2 = 0.0203) of variation in mean follicle size (F = 1.51; df = 1, 74; P = 0.223). However, regression analyses for SVL versus Class I, II, and III follicles lengths indicated a significant relationship between SVL and Class I follicle lengths (F = 5.39; df = 1, 15; P = 0.035; r^2 = 0.264). No significant relationship was found between SVL and Class II or III mean follicle lengths (Fig. 3).

Table 1. The number of female, male, and juvenile *Farancia abacura* specimens examined with an indication of their respective collection localities by state. Snakes with a SVL < 45.0 cm were consider to be juveniles. Of the 51 juveniles, 18 of these individuals were also identified as females and examined for reproductive condition. Thus a total of 129 adult and sub-adult females were examined.

	Number of Specimens			
Locality	Females	Males	Juveniles	Total
FL	2	1	0	3

Unknown	2	1	0	3
Total	111	62	51	224

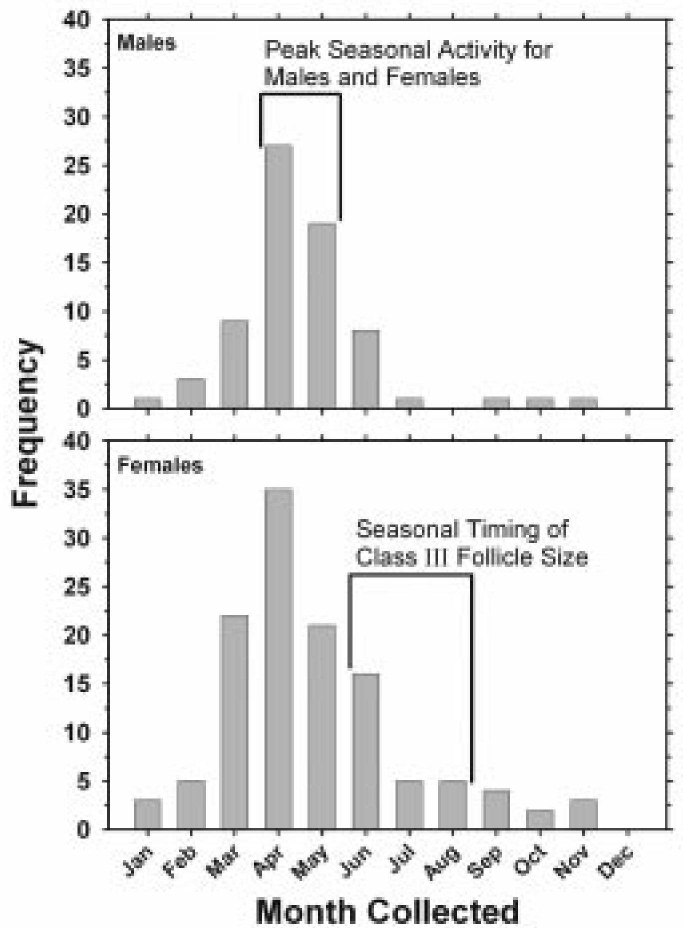

Fig. 1. Seasonal activity patterns determined from the capture records of museum specimens. Most museum specimens examined were collected between March and June, with the greatest number of males and females collected in April. These data may represent less secretive habits of the species during the months associated with seasonal reproduction. Class III follicle sizes were observed from June to August, after the period of peak seasonal activity.

Discussion

Several studies report the timing of oviposition and subsequent hatching in *F. abacura* (Goldstein 1941; Meade 1935b, 1937, 1940a, 1945; Reynolds and Solberg 1942), but little is known about seasonally dependent follicle sizes. Most museum specimens examined in this study were collected between March and June with the greatest number for females being found in April. This tendency for higher captures in April could be due to an increase in activity associated with reproductive behavior. This observation is supported by Robinette and Trauth (1992) who examined 22 male and 22 female *F. abacura reinwardtii* from Arkansas and found that reproductive cycles peaked in May and June. Although we might expect that specimen capture in spring is directly due to seasonal activity, we cannot exclude the possibility of sampling

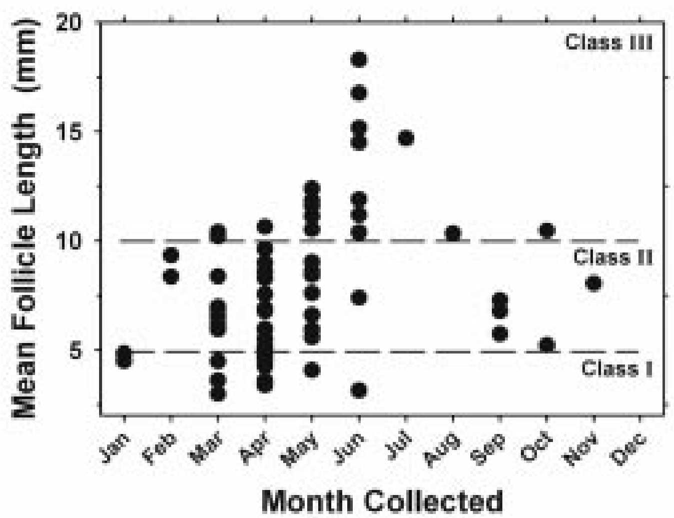

FIG. 2. Monthly distribution of mean follicle length of *Farancia abacura* (N = 76). The greatest proportion (>75%) of individuals demonstrating a Class III mean follicle size was observed in June, July, and August. Class IV was observed only in July.

bias due to greater frequency of collecting trips in spring. However, the observations of road-killed specimens may not show such a collection bias. Of the snakes examined in this study, all 14 road-killed specimens were collected during spring and early summer, thus supporting observations of seasonal activity in *F. abacura* (see also Means and Christman 1998). Lutterschmidt (unpubl. data) conducted a 12-month survey of snake activity in southeastern Louisiana, during which 33 *F. abacura* sampled were found only from April through August, with more than 85% of these captures occurring in April, May, and June. These observations of seasonal activity are similar to observations of juvenile emergence of *F. abacura* in South Carolina where 67 of 98 individuals were captured in April and May (Semlitsch 1988). Although activity is greatest in spring and summer, indicating seasonal emergence and activity, *F. abacura* has been collected throughout the year. However, Meade (1935a; 1946) indicated that they most likely hibernate between November and mid-February. Many of these differences in activity may result from observing different populations over the geographical range of *F. abacura*.

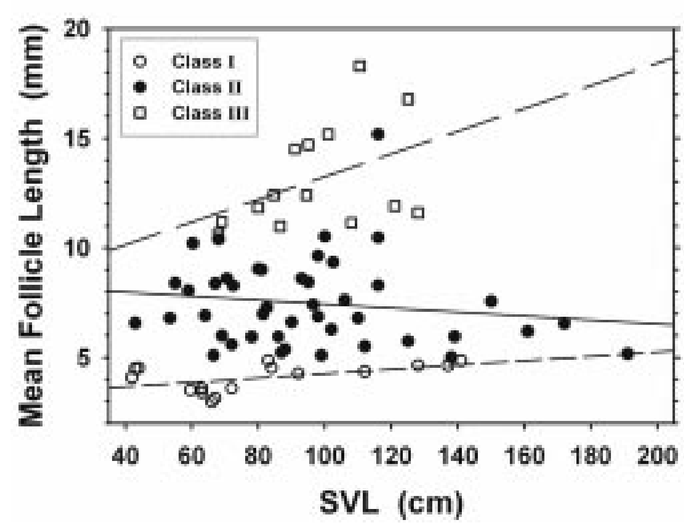

FIG. 3. Relationship between SVL and mean follicle lengths (MFL) of *Farancia abacura*. Regression results and equations: SVL vs. all MFL (F = 1.51; df = 1, 73; P = 0.223; r^2 = 0.0203; MFL = 0.016*SVL + 6.26); SVL vs. Class I MFL (F = 5.39; df = 1, 15; P = 0.035; r^2 = 0.264; MFL = 0.010*SVL + 3.27); SVL vs. Class II MFL (F = 3.20; df = 1, 42; P = 0.081; r^2 = 0.071; MFL = _0.014*SVL + 8.54); SVL vs. Class III MFL (F = 2.58; df = 1, 12; P = 0.134; r^2 = 0.177; MFL = 0.052*SVL + 8.07).

Class II follicles are prevalent throughout the year (March, April, May, August, September, October, and November). However, in June and July follicles increase in length to Class III. After reaching Class III, follicles develop rapidly to Class IV, which are ≥ 2 cm in length and occur just prior to ovulation (Kofron 1979b). Only one specimen (collected in July) of the 129 examined had an ovum in Class IV (Fig. 2). This suggests that when the ova of female mud snakes are in later developmental stages (i.e., III and IV), female snakes may become secretive and less subject to capture. Once *F. abacura* find a mate, they return to their secretive habits. This correlates with Meade's (1937, 1946) observations of July breeding habits. A road-killed gravid female from Florida (collected in August 1997, SVL = 119.0 cm) had three large ova and approximately nine additional vascularized areas in the right oviduct, indicating she had recently oviposited part of her clutch (Means and Christman 1998).

Many studies of snake reproduction have addressed the relationship between female body size and the relationship between clutch mass and clutch size (e.g., Brodie and Ducey 1989; Ford and Seigel 1989; Tinkle 1957; Kofron 1979a, 1983; Santos and Llorente 2001; Voris and Jayne 1979; White et al. 1982), finding reproductive plasticity in female life-history traits. For example, when exposed to periods of low foraging success prior to vitellogenesis, clutch mass and clutch size may decrease (e.g., Seigel and Ford 2001). However, female body size seems to have little effect on mean follicle length. Within a species, mean follicle length is simply a function of development, thus follicle size is a function of time and not female body size. We found no relationship between female body size and mean follicle length during reproduction (Fig. 3). However, upon separating out each developmental size class (i.e., Class I, II, and III), we found a significant relationship between SVL and Class I follicle size. Kofron (1979b) examined reproductive age and ovarian morphology of seven aquatic snake species in south-central Louisiana, not including *F. abacura*. He measured follicles and classified them according to the system that we used here and showed that follicles of all seven species were in Classes I and II at the end of the first reproductive year. Class III follicles were present at the end of the second reproductive year, and then rapidly enlarged to Class IV during the spring of the third reproductive year just prior to ovulation. Although we did not demonstrate a SVL-dependent mean follicle size among females, individual females most likely produce larger follicles with increasing age and body size (Betz 1963; Kofron 1979b). This might explain why we observed a significant relationship between SVL and only Class I follicles. Most of our observation for Class I follicles (56%) were from females less than 80 cm SVL.

We hope the information gathered from museum specimens and presented here aids future investigators studying the seasonal timing of reproduction in *Farancia*.

Acknowledgments.—We thank curators and staff of the Texas Cooperative Wildlife Collection at Texas A&M University, Louisiana State University Museum of Zoology, Sam Noble Oklahoma Museum of Natural History at the University of Oklahoma, Stephen F. Austin Vertebrate Museum at Stephen F. Austin State University, and Texas Natural History Collection at the University of Texas for access and use of all specimens of *F. abacura*. We thank M. L. Thies and J. L. Turk for helpful comments and sincere thanks to Carol Spencer for reviewing and providing suggestions that have helped to improve this manuscript.

A conservative estimate by Stuart et al. (2004) identified declines in 43% of all amphibian species worldwide. Three major causes were recognized as underlying these rapid global declines: overexploitation, habitat reduction, and enigmatic agents (Stuart et al. 2004). Enigmatic agents (mainly pathogens) may be responsible for driving nearly a quarter of the world's amphibian species towards rapid extinction (Stuart et al. 2004). The main relationship currently recognized between a pathogen and amphibian declines has been with the chytrid fungus *Batrachochytrium dendrobatidis* (Chytridiomycota) (Carey et al. 2003). This emerging fungal pathogen causes the disease chytridiomycosis and is responsible for amphibian declines, die-offs, and possible extinctions (Berger et al. 1998; Bosch et al. 2001; Carey et al. 2003; Daszak et al. 1999; Green et al. 2002;, Muths et al. 2003). *Batrachochytrium dendrobatidis* has been considered an aquatic pathogen because it requires water to transmit zoospores (Longcore et al. 1999) and cannot survive desiccation (Johnson et al. 2003). In wild populations of amphibians, chytridiomycosis has only been associated with aquatic habitats and surface water. We report here the first case of chytridiomycosis in a wild-caught, strictly terrestrial salamander. Our discovery expands the known ecological occurrence of this deadly pathogen into the terrestrial community, and indicates that many more amphibians, not just those associated with aquatic habitats, are potentially vulnerable to the disease.

We observed a *B. dendrobatidis* infection through histological examination in wild-caught terrestrial Jemez Mountains Salamander (*Plethodon neomexicanus*, Plethodontidae), a species endemic to the relatively dry slopes of the Jemez Mountains, New Mexico, USA. A single gravid adult female (specimen 18810; U.S. Geological Survey, National Wildlife Health Center, Madison, Wisconsin; mass: 2.57 g; SVL: 63.3 mm) was collected in a meadow with a few aspen trees (*Populus tremuloides*) (2950 m elev.). The infected salamander had typical foci of infection around the vent containing multiple zoosporangia of *B. dendrobatidis* and black flakes of unshed skin around the vent (Fig. 1A), characteristic of abnormal ecdysis (Berger et al. 1998). Cytological and histological examinations of the abnormal molt and epidermis revealed thalli and zoosporangia of *B. dendrobatidis* (Fig. 1B, 1C). In addition, a PCR-based assay, which amplifies the internal transcribed spacer regions of the rDNA cassette specific to *B. dendrobatidis* (Annis et al. 2004), confirmed the presence of DNA of *B. dendrobatidis* in skin of the ventrum and tail.

This first report of chytridiomycosis in a wild-caught, strictly terrestrial species suggests that *B. dendrobatidis* survives in terrestrial habitats. The persistence and transmission mechanisms of the pathogen in terrestrial communities remain largely unknown. It is possible that the fungus was transmitted to this salamander either by direct or indirect contact with sympatric infected aquatic amphibians. Other sympatric amphibians include Tiger Salamanders (*Ambystoma tigrinum*) and Boreal Chorus Frogs (*Pseudacris maculata*).

Although Stuart et al. (2004) concluded that enigmatic agents are primarily affecting Neotropical montane stream-associated species, it is generally accepted that surface water-associated amphibian species on all continents are at serious risk from *B. dendrobatidis.* Despite suspected declines in some terrestrial salamanders (Parra-Olea et al. 1999), and a report of chytridiomycosis in a captive terrestrial salamander (Pasmans et al. 2004), this pathogen has not been a major concern in strictly terrestrial frogs, salamanders, or caecilians because of their dissociation from surface water. The discovery of chytridiomycosis in a wild-caught terrestrial salamander significantly expands the potential host-range of *B. dendrobatidis*, suggesting that many more amphibians are at risk than previously thought.

Terrestrial communities might play a heretofore unrecognized, but important role, in the distribution, persistence, or dispersal of this epizootic pathogen. Whereas effective methods of control of *B. dendrobatidis* in sites of natural amphibian populations are unknown, attention should be directed towards limiting the spread

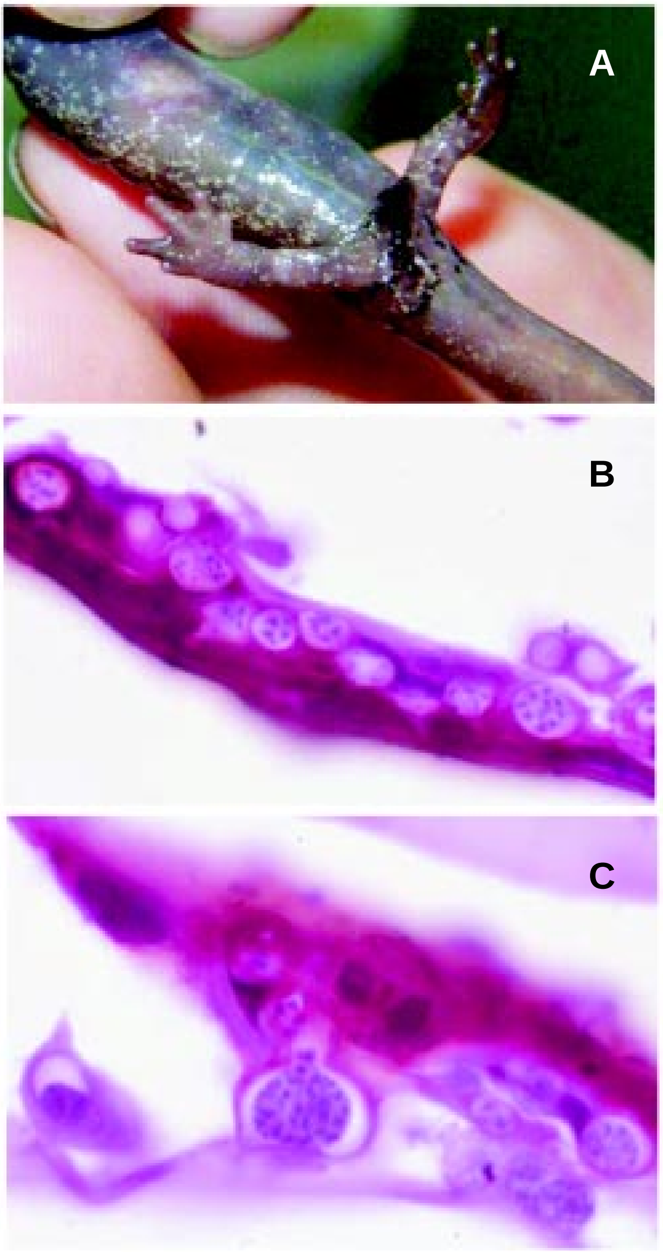

FIG. 1. Infection of *Batrachochytrium dendrobatidis* in terrestrial Jemez Mountains Salamander (*Plethodon neomexicanus*). A) Infected female with abnormal (black) spots around vent as it appeared after 11 days at 4˚C. The black foci were limited to ventral skin and consisted of abnormally retained flakes of molt (dys-ecdysis). B) Histological section (hematoxylin and eosin [H&E] stain, 1000x) of abnormal molt showing numerous spherical zoosporangia of *B. dendrobatidis*. C) the larger flask-shaped chytrid thallus at bottom center is filled with zoospores and shows a characteristic discharge pore at the 12 o'clock position (H&E stain, 1000x).

of the agent by strict biosecurity measures in the field to prevent anthropogenic transmission and dispersal. Continued and expanded efforts to monitor the status of amphibian populations worldwide, to understand the biology of this pathogen, and to investigate the complex interactions of this host-pathogen system are urgently needed to reduce global losses of amphibian species.

Description of the Tadpole of *Pseudopaludicola boliviana* (Anura: Leptodactylidae)

ARTURO I. KEHR
and
EDUARDO F. SCHAEFER
CECOAL-CONICET, C.C. 140, (3400) Corrientes, Argentina
e-mail (AIK): arturokehr@yahoo.com.ar
(EFS): eclschaefer247@hotmail.com

The genus *Pseudopaludicola* consists of frogs of small size (< 20 mm SVL [snout–vent length]) and they are distributed in the oriental region of South America, from the north of Colombia to the Province of Buenos Aires in Argentina. Frost (2004) recognized 12 species of *Pseudopaludicola*: *Pseudopaludicola boliviana*, *P. canga*, *P. ceratophryes*, *P falcipes*, *P. llanera*, *P. mirandae*, *P. mineira*, *P. mystacalis*, *P. pusilla*, *P. riopiedadensis*, *P. saltica*, and *P. ternetzi*. Lynch (1989) and Lobo (1994, 1995, 1996) studied the systematics of the genus exhaustively. In Argentina, the species of the genus *Pseudopaludicola* are *P. falcipes* (Hensel 1867); *P. mirandae* (Mercadal de Barrio y Barrio 1994); *P. mystacalis* (Cope 1867) and *P. boliviana* Parker 1927 (Lavilla and Cei 2001). The first citation of *P. boliviana* for Argentina was for the Province of Chaco (Lobo 1989, 1990).

Pseudopaludicola boliviana belongs to the *Pseudopaludicola pusilla* group, in which the included species (*P. boliviana, P. canga, P. ceratophyes, P. llanera, and P. pusilla*) have toes with T-shaped terminal phalanges. The distribution of these species in South America is widespread. *Pseudopaludicola boliviana* is distributed in disjunct regions of eastern Colombia, northern Brazil (Roraima), and southern Venezuela through Guyana to Surinam and French Guiana, eastern Bolivia, Paraguay, southwestern Brazil, and northern Argentina; *P. canga* is known only from the type locality, Serra dos Carajás, municipality of Marabá, state of Pará, Brazil; *P. ceratophyes* is known only from Leticia, Colombia; *P. llanera* in northeastern Colombia and adjacent Venezuela in the drainage of the Río Orinoco, and *P. pusilla* is distributed in the lower and middle Magdalena River valley and the Caribbean lowlands of northern Colombia and adjacent Venezuela.

In Argentina, *P. boliviana* is distributed in the provinces of Formosa, Chaco and northern Santa Fé (Lobo 1992). Recently, Duré et al. (2004) also cited this species for the Province of Corrientes, the first record east of the Paraná River. Until the present**,** tadpoles of species belonging to the *Pseudopaludicola pusilla* group have not been described. In this paper, we describe *P. boliviana* tadpoles from Corrientes, Argentina.

Materials and Methods.—The tadpole description of *P. boliviana* is based on specimens collected in a rice field located 30 km NE of the city of Corrientes (27˚30'S; 58˚45'W), Province of Corrientes, Argentina. Specimens (N = 16) were collected by us on 4 December 2003. A subset of those individuals (N = 10) was raised in the laboratory through metamorphosis to confirm the species identification. The remaining tadpoles (N = 6) were preserved in 10% formalin.

Descriptive terminology follows that of Altig and McDiarmid

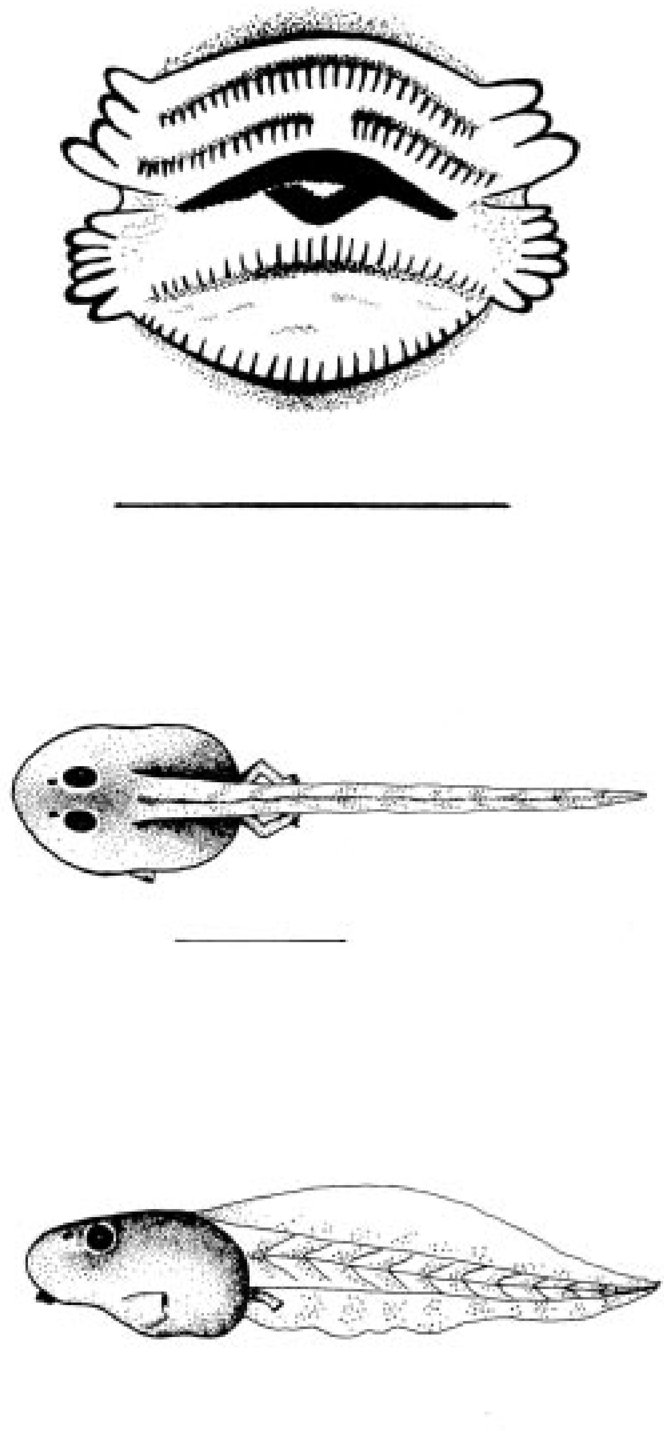

FIG. 1. Oral disc, dorsal and lateral views of *Pseudopaludicola boliviana* tadpole, CECOAL 005, from Corrientes, Argentina. Gosner stage 36. Scale line: 1 mm, 5 mm, and 5 mm (top to bottom).

(1999) and Kehr and Williams (1990). The morphometric variables considered are those suggested by Kehr et al. (2004). Measurements were taken with dial caliper and recorded to the nearest 0.1 mm; these variables are abbreviated as follows: TL (total length), BL (body length), TaL (tail length), BW (body maximum width), BWE (body width at eyes), BWN (body width at nostrils), BH (body

maximum height), FH (fin height), TMH (tail muscle height), RSD (rostro–spiracular distance), SPD (spiracular–posterior distance), FN (fronto–nasal distance), NO (narial–ocular distance), N (nostril diameter), E (eye diameter), EN (extranarial distance), IN (internarial distance), EO (extraorbital distance), IO (interorbital distance), ODW (oral disc width), RG (rostral gap), MG (mental gap). Tadpoles were staged using Gosner's table of normal development (Gosner 1960). Drawings were made with the aid of a camera lucida attached to a Wild M3C stereomicroscope.

Results and Discussion.— The specimen illustrated (CECOAL 005) (Fig. 1) is at Gosner stage 36 and has the following measurements in mm: TL = 18.8, BL = 7.0, TaL = 11.8, BW = 4.8, BWE = 4.3, BWN = 3.4, BH = 3.8, FH = 4.2, TMH = 1.7, RSD = 4.5, SPD = 2.8, FN = 1.0, NO = 0.4, N = 0.1, E = 1.0, EN = 1.0, IN = 0.8, EO = 2.4, IO = 0.9, ODW = 1.3, RG = 0.9, MG = 0.9. Table 1 summarizes the measurements of tadpoles in different stages collected at the same time with the tadpole described here.

TABLE 1. Measurements (in millimeters) of *Pseudopaludicola boliviana* tadpoles from Corrientes, Argentina. The individuals (N = 5) were collected together with the tadpoles described in the text. Tadpoles were staged according to Gosner (1960).

	Stage				
Morphometric variables	30	31	41	41	41
TL (total length)	9.6	10.4	19.3	18.4	19.6
BL (body length)	3.8	4.2	7.0	6.8	7.1
TaL (tail length)	5.8	6.2	12.3	11.6	12.5
BW (body maximum width)	2.7	2.7	5.2	4.7	4.8
BWE (body width at eyes)	2.3	2.5	4.3	4.1	4.2
BWN (body width at nostrils)	1.8	2.0	3.2	2.9	3.2
BH (body maximum height)	2.1	2.3	4.0	3.6	3.5
FH (fin height)	1.6	1.6	3.4	3.7	3.9
TMH (tail muscle height)	0.6	0.8	1.8	1.6	1.3
RSD (rostro-spiracular distance)	2.2	2.9	4.3	4.4	4.6
SPD (spiracular-posterior distance)	1.3	1.2	2.5	2.4	2.5
FN (fronto-nasal distance)	0.5	0.7	1.0	0.9	1.0
NO (narial-ocular distance)	0.2	0.2	0.2	0.4	0.3
N (nostril diameter)	0.1	0.2	0.3	0.2	0.2
E (eye diameter)	0.6	0.6	1.2	1.1	1.2
EN (extranarial distance)	0.6	0.6	1.5	1.2	1.2
IN (internarial distance)	0.5	0.4	0.8	0.8	0.9
EO (extraorbital distance)	1.5	1.4	2.9	2.7	3.0
IO (interorbital distance)	0.5	0.5	1.0	0.9	1.0
ODW (oral disc width)	0.6	0.7	1.3	1.2	1.1
RG (rostral gap)	0.5	0.6	1.0	0.9	1.0
MG (mental gap)	0.3	0.6	0.7	0.6	0.6

Tadpoles of *P. boliviana* have an ovoid body, wider than high (BW/BH = 1.3). Snout rounded in lateral and dorsal views; nostrils dorsal, located nearer eyes than snout; eyes dorsolateral. Spiracle single, sinistral, and ventrolateral, visible in dorsal view; vent tube 1.8 mm long, positioned and opening medially; tail 63% of total length; the maximum tail fin height is greater than that of the body; dorsal fin extending slightly onto body, and is higher than ventral fin; tail tip pointed-rounded.

Oral disc positioned anteroventral to ventral; single row of 3–4 large marginal papillae on each side of the rostral gap and six large marginal papillae on each side of the mental gap, with a small gap separating the two groups of marginal papillae on each side; mental gap 0–0.6 times lower than rostral gap; labial tooth row formula 2(2)/2 (Fig. 1); labial teeth, with two to four cusps; length of tooth rows: Al = 0.9 mm, A2 = 1.0 mm, gap of A2 = 0.2 mm; P1 = 1.1 mm, P2 = 0.9 mm; upper jaw sheath approximately 0.7 mm long; upper jaw sheath and lower jaw sheath serrated; upper jaw sheath broadly arch-shaped, lower jaw sheath V-shaped.

In life, dorsally, the body is brown with scattered dark spots; small dark spots start at the caudal musculature; two dark spots on each eyelid; iris with scattered golden spots; laterally, body pale brown, and base of spiracle pigmented; the caudal musculature with small bands darker among each muscular package; the dorsal fin clearer than ventral fin; ventral fin with scattered golden spots and melanic bands; ventrally, intestinal coils not visible, intestinal area with golden color; throat with scattered golden spots. In preservative, body light olive or gray with small dark and reticulate spots; throat semitransparent and intestinal coils barely visible through skin; tail fins transparent with small, black patches of melanin mainly on the ventral fin.

This is the first tadpole described for a species of the *Pseudopaludicola pusilla* group. In Corrientes, in the same area where *P. boliviana* is very common, there were also developing tadpoles of *P. falcipes*. Lamentably, information is scarce about the morphology of *P. falcipes* tadpoles and only the oral disc features are well detailed (Barrio 1945, 1953; Cei 1980). The differences between the tadpoles of these two syntopic species are: (1) *P. falcipes* without mental gap (*P. boliviana* present) and, (2) *P. falcipes* with labial tooth row formula 2(2)/3 (*P. boliviana* 2(2)/2). Lavilla and Cei (2001) cited two additional species occurring in the Province of Corrientes: *Pseudopaludicola mystacalis* (Cope 1867) and *P. mirandae* Mercadal de Barrio and Barrio (1994). The tadpoles of these species are unknown.

Until now, considering the tadpole described here, there are only three species of the genus *Pseudopaludicola* with the tadpoles described: *P. boliviana* (described here), *P. falcipes* (Barrio 1945, 1953) and *P. ternetzi* (Lobo 1991). In reality, the tadpole described by Lobo (1991) was considered a posteriori as *P. ternetzi* (Lobo 1994) because this author described this tadpole as *P. mystacalis*. It is probable that *P. ternetzi* is not present in Argentina as its known range is otherwise restricted to Goias, Brazil; nevertheless we will compare the morphological features between *P. boliviana* and *P. ternetzi* tadpoles: (1) both tadpoles share the same labial tooth row formula 2(2)/2; (2) *P. ternetzi* lacks a mental gap (*P. boliviana* present) and, (3) total length and body lengths are similar in the two tadpoles (stages 36–37) (*P. ternetzi*: 20.8

mm and 7.3 mm respectively; *P. boliviana*: see Table 1).

Acknowledgments.—We are grateful for the critical review and suggestions on the manuscript by Martha L. Crump and Ronald Heyer. The authors are grateful to the Consejo Nacional de Investigaciones Científicas y Técnicas – CONICET – from Argentina for financial support.

Trapping animals without the use of bait reflects the density of the captured species and the level of that species' activity on the surface sampled. Trap capture with bait additionally reflects the attraction of the bait, environmental conditions affecting bait sensory cue detection, and the motivation level of the animal, among other variables. When the variable of interest is population density, the other factors (activity level, habitat, motivation, etc.) are nuisance variables that increase variance, but do not necessarily bias the relationship between the chosen index (typically captures/trap h) and the phenomenon of interest (population density). The strength of each such relationship is a crucial methodological attribute. Unfortunately, the precision of the statistical correlation between trap capture success and population density is rarely known. We are not aware of any study that has quantified the precision of population estimation using trap capture of reptiles. The development of total removal sampling (Rodda et al. 2001a) has made possible the estimation of this relationship for small herpetofaunal assemblages. Using total removal sampling, we sampled the herpetofauna of islands of the Pacific Ocean, Indian Ocean, and the West Indies in small (10 × 10 m) plots. By preventing immigration/emigration while removing all aboveground vegetation, we were able to completely enumerate (census) the absolute density of each species in the plots. We estimated relative population densities for small lizards on the basis of glueboard capture rates obtained concurrently from traps set in a ring surrounding each total removal plot. Given the close geographic correspondence between the sample areas, we expected a tight correlation between glueboard capture rates and absolute population densities.

The precision of a bivariate relationship is traditionally characterized by r^2, the squared correlation coefficient. We report this value, but in addition report a new metric of population estimation precision: percentile range of the population densities corresponding to the 95% confidence limits of a midrange relative population density estimate. One weakness of r^2 as a metric of precision is that it is a ratio that reflects changes in both the numerator and denominator. Without changing the precision of a relationship, r^2 can be increased by extending the range of values being correlated. A more intuitive weakness of r^2 in this case is that it is measured in units that do not relate directly to the feature being estimated. That is, it does not express uncertainty about popula-

tion density estimate in terms of population density.

For a specific system, confidence limits can be expressed in terms of absolute density (e.g., 8–14/ha). Unfortunately, such ranges cannot be used to compare the precision of estimates among different species or habitats. Typical measures of dispersion, such as standard errors, assume normality. Densities are unlikely to be normally distributed—ours were not. Percentile ranks, because they make no assumptions about the shape of the underlying distribution, are more general.

Consider an ideal linear relationship between a relative and absolute population abundance measure. In a hypothetical example, trap capture yield varies 0–100 captures/trap h. At midrange, about 50 captures/trap h, the true density of our hypothetical taxon is about 10/ha, which is the 50th percentile of known abundance (which in this example ranges 0–25/ha). Furthermore, the 95% upper and lower confidence limits (CL) of our estimate are 8/ha and 14/ha, which are the 40th and 60th percentiles of known abundance respectively. Thus a midrange relative population estimate provides us with the knowledge that 95% of the time the true density of a population producing 50 captures/trap h will fall within the 40th–60th percentile range, and the single best estimator is at the 50th percentile, or 10/ha. A less precise relationship might have indicated only that the true value was in the range of 25th–75th percentiles, and a worthlessly imprecise measure would cover the full range of possibilities: 0–100th percentile. The central question of our study was: what percentile range of true densities is associated with the 95% confidence limits on a relative population measure at midrange?

The answer to this question is, unfortunately, context specific. We consider three possible sources of variance—species, habitat, and island—within the context of our specific sample size. A different sample size would produce different degrees of precision, but our sample sizes are typical and can therefore be used to illustrate the types of challenges facing an effective relative population measure.

Relative population estimators, indices, or counts are assumed to be proportional to true density. That is, if a later count were three times that of an earlier count, we could assume that the true density has increased threefold. If that condition is met for all possible changes, the regression of true density on sample density will form a straight line that passes through the origin, the slope reflecting the detectability of the species. The slope represents average detection multiplier (= $\hat{N}/\bar{n}$); alternately, the inverse of slope represents average detection fraction or $\hat{p}$ (= $\bar{n}/\hat{N}$), where $\hat{N}$ is the best estimator of absolute abundance and $\bar{n}$ is the average index value (in our case, glueboard capture rate). If the detection fraction ($\hat{p}$) is constant over the range of densities considered, the points will lie along a line radiating from the origin. A y-intercept deviating significantly from zero indicates inconstancy in the detection fraction, and therefore a relative population estimator that will not be proportional. In our experience, the detection fraction tends to be reduced at low population densities, leading to a positive y-intercept. Inconstancy in the detection fraction will produce bias in population estimates, but the bias can be eliminated if the form and magnitude of the detection fraction inconstancy is quantified. We begin this process by quantifying the direction and magnitude of y-intercept deviations from zero.
